**Importance.**—In general, adult tapeworms are well-adjusted parasites, doing little obvious harm to their hosts. Even in heavy infestations, except for rare blockage of the intestine, there is no clear-cut evidence that serious damage is done. In Europe and the Americas, tapeworm infestations of man have been greatly reduced as a consequence of routine meat inspection. But where sanitation is poor and meat eaten undercooked, the incidence of the commoner tapeworms is high: in parts of Africa much of the population is infected with beef tapeworm (*Taenia saginata*); locally in the Baltic countries almost all of the population is infected with the broad fish tapeworm (*Diphyllobothrium latum*, or *Dibothriocephalus latus*); in parts of the southern United States up to 2% of the population may be infected with the dwarf tapeworm (*Hymenolepis nana*).

Larval stages can seriously damage the host. A certain larval stage (coenurus) of the gid parasite of sheep (*Multiceps multiplex*) usually lodges in the brain of sheep. Fluid-filled hydatid cysts of *Echinococcus* may occur almost anywhere in the body of sheep. Hydatids of the liver, brain, or lung of man are often fatal and have been most widely studied in Argentina, Australia, China, and Iceland. Infestation occurs only where man lives in close association with his dogs, and the dogs have access to infected sheep for food.

**General Form.**—A nonliving cuticle, which protects against the host's digestive enzymes, covers the tapeworm's body. It is secreted by the underlying cells of the subcuticula and is intimately associated with the dermal circular and longitudinal muscles. The internal organs lie in a spongy tissue (parenchyma), which in most species contains scattered chalk bodies (microscopic nodules of calcium and magnesium phosphates and carbonates). Both circu-

FIG. 1.—LIFE CYCLE OF BROAD FISH TAPEWORM (*DIPHYLLOBOOTHRIUM LATUM*)

lar and longitudinal muscles are present in bands, bundles, or sheets deep in the parenchyma.

The anterior headlike scolex of segmented forms serves as an organ of attachment; it is armed with suckers, phyllidia (leaflike projections), or bothria (sucking grooves), and may also bear hooks or spines on the attachment organs or on a muscular pad called a rostellum. Behind the scolex lies a region of cellular multiplication, the zone of growth, which buds off the proglottids. The cells of the parenchyma give rise to the organs as the proglottid is pushed away from the zone of growth by the new proglottids being formed; thus the proglottid farthest from the scolex is the oldest.

The nervous system in the scolex consists of a number of ganglia, commissures, and connectives from which arise the special nerves passing to the attachment organs and the two principal nerve cords of the strobila, which run a lateral course throughout the entire length of the worm. The two cords are bound together at the anterior end of each proglottid by a dorsal and ventral commissure arising from ganglia, and there is a nonganglionated commissure present at the posterior end of each proglottid. In addition, a nerve net in the subcuticular communicates with a dorsal and ventral nerve.

The excretory, or osmoregulatory, system is composed typically of two pairs (dorsal and ventral) of longitudinal canals, coursing through the strobila, with transverse vessels connecting the right and left trunks at the posterior end of each proglottid; a loop connects the dorsal and ventral vessel of each side in the scolex. Minute ducts lead from flagellated flame cells to the vessels.

The male reproductive organs usually mature first, and cross-fertilization of proglottids of the same or different individual is the rule, although it is possible for self-fertilization to occur (i.e., within the proglottid). The male duct and the vagina may open side by side into a common atrium. There is considerable variation in the position of the openings. In unsegmented forms they may be terminal, subterminal, or ventral; while in segmented forms they may be ventral or lateral. The essential organs of the genital apparatus do not differ greatly from those of other groups of flatworms.

The oviduct leads from the ovary to the Mehli's gland, where it may be met by an extension from the vagina prior to

entering the gland or just after entering. A duct from the "yolk glands" (vitellaria) joins this fused duct, and the fertilized eggs enclosed in a shell leave the gland to be stored in the uterus. In some species the ripened eggs pass from the uterus into the proglottid, which eventually detaches as an egg packet; in some, the uterus has a separate opening, releasing eggs to the exterior directly.

**Life Cycle.**—The embryo develops within an eggshell, which in some species has a lid (operculum) that comes off at the time the egg hatches. In other forms, the shell must be digested away in the intestine of a host. The fertilized egg develops into a larva that bears hooks and is called an onchosphere. Eggs with opercula usually hatch in water, releasing the onchosphere, which in such cases is surrounded by a loose ciliated coat. This free-swimming larva (coracidium) cannot feed and thus is short lived; if, however, it is eaten by the proper intermediate host it continues its development.

Among the orders Pseudophyllidea and Trypanorhyncha, some species produce coracidia, but in most of the known life histories in these orders, and in the Tetracophyllidea, the eggs are not operculated and must be eaten by a crustacean. In either case, the onchosphere is released in the digestive tract of the host; with the aid of its hooks it pulls apart the cellular lining of the intestine wall and passes into the body cavity, where it grows as a proceroid. When the infected crustacean is eaten by the next host, the proceroid is released and, according to the species, either moves into the tissues or remains in the intestine of the second host. A cyst may form around the larva if it localizes in the tissues. The encysted larva then undergoes further growth and a loss of the larval hooks; the scolex forms and the larva is called a plerocercoid. In some species this is merely a growth stage that takes place in the intestine of the final (definitive) host.

The broad fish tapeworm of man has a uterine opening and eggs are shed continuously. These eggs hatch in water, and the coracidia are eaten by small crustaceans such as *Cyclops*, in which the proceroid develops. The plerocercoids are found in trout, perch,

FIG. 3.—A MATURE PROGLOTTID OF THE PORK TAPEWORM (*TAENIA SOLIUM*)

pike, and other freshwater fishes that eat microcrustaceans. The adult worm, which may attain a length of 30 ft. or more has a worldwide distribution wherever raw or partially cooked fish are eaten. For the development of this species and others related to it, two successive changes of host are required. The larval forms known as spargana, which occur in many land vertebrates, including man, have been shown to be the plerocercoids of pseudophyllidean worms of the genus *Spirometra*, which are primarily parasitic as adults in catlike carnivores and have a life history similar to *Diphyllbothrium*.

Cyclophyllidean life histories include two larval stages, i.e., the onchosphere and the "bladder worm" (cysticercus). The latter is the infective or preadult stage. While arthropods (crustaceans, insects, mites, etc.) are the intermediate hosts for most species, the cyclophyllideans of carnivorous mammals, and also of man, usually utilize vertebrates for the intermediate host. Onchospheres of the beef tapeworm of man are released from the egg in the digestive tract of cattle. They migrate into the musculature, where each grows into a small bladder in whose wall a depression or invagination appears on the side opposite to the embryonic hooks. The scolex develops at the bottom of this invagination; once the suckers are fully formed, the cysticercus is infective. When raw or imperfectly cooked beef containing cysticerci is eaten by a human, the bladder is digested off, the scolex is evaginated, and the worm begins to produce proglottids from the region that originally connected the scolex to the bladder. Another human parasite, the pork tapeworm, has a similar development but has a

rostellum armed with hooks and utilizes the pig as an intermediate host.

Other frequently encountered members of the genus *Taenia* are *T. pisiformis* of the dog, with the rabbit as the intermediate host, and *T. taeniaeformis* of the cat, with mice and rats as intermediate hosts. Asexual reproduction with the production of additional scolices occurs in some cyclophyllidean species. In the gid parasite of sheep the inner lining of the bladder produces a large number of scolices, each capable of developing into an adult worm if ingested by a dog or other suitable host. Such a larva is called a coenurus. Jackrabbits in Utah and Nevada frequently contain large numbers of coenuri of *Mul-*

CLAUDE VILLIE, "GENERAL ZOOLOGY," SECOND EDITION, REPRODUCED BY PERMISSION OF W. B. SAUNDERS COMPANY

FIG. 4.—THE PORK TAPEWORM (*TAENIA SOLIUM*). INSET SHOWS THE HEAD

*ticeps serialis* in the muscles of the thighs. The adult tapeworm in this case occurs in coyotes but can infest dogs, foxes, and other canids. Asexual reproduction during the bladder-worm stage is greatest in *Echinococcus granulosus*, a tiny tapeworm of dogs and their relatives. The larval stage, called a hydatid, produces daughter bladders internally and sometimes externally. These daughter bladders may contain another generation of bladders. Since the inner walls of the bladders produce a number of scolices, each hydatid can result in hundreds of tapeworms if eaten. Hydatids occur in sheep, cattle, pig, and sometimes man and can grow to be larger than a baseball.

Houseflies and earthworms are the intermediate hosts for several tapeworms of fowl. *Dipylidium caninum*, a common parasite of dogs and cats, passes its cysticercus stage in fleas or in the louse *Trichodectes*. The louse is capable of swallowing the eggs of the worm, but the adult flea cannot. Fleas become infected during their larval period, the eggs, when eaten, hatching in the intestine and the onchospheres migrating through the wall and into the body cavity. Development to the cysticercus stage does not occur until the flea metamorphoses as an adult. Man as well as dogs and cats can become infested if

infected fleas are swallowed. Important cattle and sheep tapeworms such as *Moniezia expansa* pass the cysticercus stage in mites as do certain tapeworms of rabbits. *Hymenolepis nana*, the commonest tapeworm occurring in man, does not require an intermediate host though it can pass the cysticercus stage in beetles or fleas. If man becomes infected by swallowing eggs, the cysticercus stage occurs in the crypts of the wall of the small intestine, and the larva when mature evaginates, projecting into the intestine, and grows to adulthood.

**Classification.**—There are two subclasses: the Cestodaria, unsegmented parasites of the digestive tract and coelom of fishes with one species in the coelom of an Australian turtle; and the Cestoda. The latter group contains usually segmented species parasitic in the digestive tract; their larvae hatch from the egg and have six larval hooks instead of the ten found on cestodarian larvae. One major group of the Cestoda has three larval stages and follicular vitellaria or a ventral vitellarium. It includes the following orders: Tetraphyllidea, primarily parasites of cold-blooded vertebrates, with scolex variably armed; Pseudophyllidea, parasites of warm- and cold-blooded vertebrates, with scolex usually armed with bothria; Trypanorhyncha, parasites of elasmobranch fishes, with scolex armed with bothria and four eversible proboscides, which are armed with hooks and spines.

A second group of the Cestoda has a compact dorsal vitellarium and two larval stages and consists of the order Cyclophyllidea, primarily parasites of warm-blooded vertebrates; scolex with four suckers, and frequently an armed rostellum.

**TAPIR**, a large, forest-dwelling, hoofed mammal that bears a strong likeness to a large pig, though there is no zoological relationship. There is only one genus, *Tapirus*, which constitutes the family Tapiridae, perissodactyl (q.v.) order. The geographical distribution of tapirs is peculiar: several species and subspecies are

F.L.A. FROM RAPHO-GUILLETTE

SOUTH AMERICAN TAPIR AND YOUNG

found in Central and South America, and one in southeast Asia. Fossil remains from Europe, China, and North America show that tapirs were once widespread; and that the extinction of intermediate forms has isolated the living species. The American species (*T. terrestris*, *T. roulini*, and *T. bairdi*) are all uniformly brownish, but the Asiatic, or Malayan, tapir (*T. indicus*) has black fore- and hindquarters and a whitish body; the young of all species are dark, with yellow and white stripes and spots, a pattern lost in six to eight months after birth.

The tapir's body, which can be 6 ft. (1.8 m.) long and weigh up to 600 lb. (304 kg.), is stout and barrel shaped; the tail short; and the nose and upper lip prolonged to form a short, highly mobile proboscis. The body is covered with short, harsh hair, which forms a short mane on the crest of the neck. The animal has four front and three hind toes.

There is no fixed mating season. In the American species a single young is born after a gestation of about 11 months; its life span is up to 30 years. Tapirs are exclusively vegetarian, eating leaves and water plants. In captivity they are generally very docile and friendly. They are on the whole solitary, and active at night. The flesh of tapirs is esteemed by the natives of the countries they inhabit. The Malayan species is in danger of extinction; the American species is still numerous. (L. H. M.)

**TAPS AND DIES:** see MACHINE TOOLS.

**TAPTI**, a river of western India. It rises in the Betul district of Madhya Pradesh and flows westward between two spurs of the Satpura Range, across the Khandesh Plateau in Maharashtra, and through the Plain of Surat in Gujarat to the Arabian Sea. It has a total length of about 436 mi. (702 km.) and drains an area of 25,200 sq.mi. (65,300 sq.km.). For the last 32 mi. (52 km.) past the port of Surat it is tidal, but is navigable only by small vessels. The port of Swally at its mouth, famous in Anglo-Portuguese history, is now deserted, having become silted up like the other ports in the Gulf of Cambay. The Tapi flows roughly parallel to the larger Narmada River to the north, from which it is separated by the main part of the Satpura Range. The two river valleys and the intervening range form the natural barrier between northern and peninsular India. (L. D. S.)

**TAR:** see COAL TAR; CREOSOTE; TARS, LOW-TEMPERATURE.

**TARA** (Old Irish TEMUIR), a low (c. 507 ft.) (155 m.) hill in County Meath, Ire., occupies an important place in Irish legend and history. Already in prehistoric times it was, probably, a cult centre, for the earliest remains so far identified there consist of a small passage grave (excavated 1955–59) dated to about 2100 B.C. It is known as *Dumha na nGiall* (Mound of the Hostages), a name that, like those applied to the other monuments on the hill, is derived from medieval topographical tracts. Numerous

inserted Bronze Age burials were found in the earth mound that covered the grave. The mound lies just within the perimeter of a huge oval enclosure called *Ráth na Ríogh* (Rath of the Kings), near the centre of which are two conjoined earthworks: one called *Forradh* (Royal Seat), the other *Teach Cormaic* (Cormac's House). On the latter is a pillar stone, said to have stood formerly on the Mound of the Hostages and sometimes equated with the *Lia Fáil*, or inauguration stone of the kings of Tara. The other principal sites are a large ring fort known as *Ráth Laoghaire* (Laoghaire's Rath); two circular enclosures called *Claoin Fhearta* (Sloping Graves) and *Ráth Gráinne* (Gráinne's Rath); and a great rectangular earthwork, c. 750 ft. long, which is usually identified as the *Teach Míodhchuarta* (House of the Mead-circling) or banquet hall referred to in ancient Irish literature. Of the remaining monuments, *Ráth na Seanad* (Rath of the Synods), excavated 1952–53, proved to be a ritual site that had undergone four successive enlargements between the 1st and 4th centuries A.D. The main earthworks on the hill are probably to be attributed to the first five centuries of the Christian era when Tara was the seat of a dynasty of Uí Néill kings who appear to have abandoned it in the 6th century. (A. T. Ls.)

**TARAFAH** ('AMR IBN AL-'ABD AL-BAKRI), Arab poet of the 6th century and author of one of the odes in the *Mu'allagat* (q.v.). After a wild and dissipated youth spent in Bahrain, and after fighting in the war between the tribes of Bakr and Taghlib, he went with his uncle Mutalammis, who was also a poet, to the court of the king of Hira, 'Amr ibn Hind (d. 568–569), and there became companion to the king's brother. Having ridiculed the king in some verses, he was sent with a letter to the ruler of Bahrain and, in accordance with the instructions contained in the letter, was buried alive.

Tarafah's collected works were ed. by W. Ahlwardt in the *Divans of the Six Ancient Arab Poets* (1870). For a summary of his life and an Eng. trans. of his *mu'allagah*, see A. J. Arberry, *The Seven Odes* (1957).

**TARANTELLA**, an Italian folk dance in rapid 6/8 time, danced in couples and characterized by light quick hops and tapping foot movements. Its origin is connected with tarantism, a disease or form of hysteria that appeared in Italy in the 15th–17th centuries and was obscurely associated with the bite of the tarantula spider: victims seemingly were cured by frenzied dancing. The name tarantella may be more directly derived from Taranto, a town located in the region where tarantism was especially prevalent. The tarantella appears in many ballets, including *Napoli, La Tarentule*, and *La Boutique Fantasque*. (LN. ME.)

**TARANTO** (ancient Greek TARAS; Latin TARENTUM), a port and important naval base of Puglia (Apulia), Italy, and chief town of Taranto Province, lies on the north inlet of the Gulf of Taranto, 50 mi. (80 km.) SSE of Bari. Pop. (1961) 200,974. The old part of the city (Città Vecchia) occupies a small island that almost entirely blocks the channel between the outer and inner harbours, Mare Grande and Mare Piccolo. It is joined to the newer sections on the mainland by two bridges, one of which, the Ponte Girevole, revolves to permit shipping to enter the Mare Piccolo. The mainland parts consist of the industrial Borgo (northwest), with the railway station, and the Città Nuova (southeast). The old city stands on the site of the Acropolis of Taras and contains the Aragonese Castle (rebuilt in 1480 and subsequently enlarged), the 11th-century Romanesque Cathedral of S. Cataldo (with a Baroque facade and early 15th-century campanile with mullioned windows), and the Church of S. Domenico Maggiore (1302), with a Romanesque-Gothic facade, an imposing portal, and a rose window. The Città Nuova contains the Arsenal (1803); the Banca d'Italia; the post office; the Government Palace (1896); the city library; the Meteorological and Geophysical Observatory (1905); the National Museum (with its 18th-century cloister of S. Pasquale), which houses an important archaeological collection covering Taranto and the rest of Apulia; the State Institute of Marine Biology (1931); and the Villas Garibaldi and Comunale Peripato. In the Mare Piccolo there is much oyster and mussel farming, and there is fishing with the ebb of the tide. Industries include canning and food processing, shipbuilding, and the manufacture of chemicals and bricks. Railways link the town with Brindisi, Metaponto, and Bari. (M. T. A. N.)

**History.**—At Scoglio del Tonno, northwest of Taranto, there are traces of Mycenaean Greek trade. In the 8th century B.C. (the traditional date is 706 B.C., but it may well have been earlier), Greek settlers from Sparta and Laconia conquered the Messapian village of Taras, on the river of the same name (modern Tara), and founded a new Taras on the peninsula (cut in 1480 by a canal) that lay between the Mare Piccolo and the Mare Grande. Taras soon became one of the leading cities of Magna Graecia, despite a catastrophic defeat by the native Iapygians c. 473; Callipolis (Gallipoli) and Hydrus (Otranto) were founded from Taras, as, in 433, was Heraclea (q.v.).

At the time of Archytas (q.v.; 4th century B.C.), the great philosopher and scientist, Taras reached its maximum splendour; it was then the chief city of the Italiote League, formed to protect the Greek cities scattered along the coast of the Ionian Sea from the recurrent attacks of the Lucanians and Iapygians. But with the death of Archytas, the league unfortunately lost its commander and eminent strategist (who, it is said, never lost a battle), and the Lucanians and Bruttii, assisted by Iapygians and Messapians, thereupon declared war on Taras itself, which turned first for help to Archidamus III, king of Sparta (killed 338), and then to Alexander the Molossian, king of Epirus (killed c. 330). But neither these nor subsequent hired defenders were effective, and the defeat of a Roman fleet off Taras in 282 led to war with the Romans; despite an appeal (281) to Pyrrhus (q.v.), king of Epirus, Taras finally submitted to them (272). During the Second Punic War most of Taras fell into the hands of Hannibal (213–212), but the consul Fabius Maximus recaptured and plundered it (209). The city, known under the Romans as Tarentum, although again confirmed as an allied city and obtaining a constitution with a senate and decurions, quadrumvirs, and aediles, never again held the right of minting coin. Some colonies, including Neptunia at Tarentum (123), were founded for discharged Roman legionaries, and many Roman families moved to Tarentum in search of a fortune. The town declined under the Roman Empire, despite attempts to repopulate it. (AN. MO.; C. DR.; X.)

From the 6th to the 10th century, Tarentum changed hands repeatedly between Goths, Byzantines, Lombards, and Arabs. The Arabs destroyed the city and enslaved the inhabitants in 927; it was rebuilt in 967 by the Byzantine emperor Nicephorus II. Robert Guiscard captured it c. 1060, and it became part of the Norman territory in southern Italy; Bohemund (q.v.) became prince of Taranto, and it served as a point of departure for Crusaders. (For its subsequent rulers, see NAPLES, KINGDOM OF.) It was fortified by Don John of Austria and during the late 16th and 17th centuries was repeatedly attacked by the Turks.

The French acquired Taranto by the Peace of Florence (1801); Napoleon created Marshal MacDonald duke of Taranto in 1809, and it was a French naval base during the Napoleonic Wars. After 1815 it was part of the Kingdom of the Two Sicilies.

After its union with Italy in 1860, Taranto became one of the most important strongholds of the Italian Navy. During World War I the British, French, and Italian fleets had bases at Taranto, and it was a meeting place for those divisions that fought at Salonika and in Macedonia and that effected the rescue of the Serbian Army. During World War II the naval base was heavily and effectively bombed (Nov. 11–12, 1940) by carrier-borne British planes; British landing forces were unopposed when they occupied the city on Sept. 9, 1943. (M. T. A. N.; X.)

**Ancient Remains.**—The Greek polis (which stood on the site of the present Città Nuova) was protected on the east by a ditch (the so-called *canalone*) and by solid walls of thick square blocks, remains of which were brought to light under the present Carmine farmhouse and in the Chiappari area on the Mare Grande.

Apparently the polis was separated from the Acropolis (also called the Rocca, corresponding roughly to the present Città Vecchia) by another wall; however, no trace of this was found during the construction of the present navigable canal. All these walls must have had fortified gates; ancient sources name several gates and streets, not all of which have been identified. The temples, of which there probably were many, remain undiscovered. Of the Temple of Apollo only a deposit of hundreds of statuettes of the

god have been found, and two imposing Doric columns are all that remain of a temple presumably dedicated to Poseidon. There is little information regarding the civil buildings. Like Sparta, Taras rose from the union of small groups of houses, each with its own little cemetery; this explains the tombs of that period, which are scattered over the area of the ancient polis. These tombs yielded imported Greek vases (proto-Corinthian, Corinthian, proto-Attic, and black-figured Attic; also, very rare, red-figured Attic) and, from the beginning of the 4th century B.C., Italiote vases made by local craftsmen, imitations of figured Greek vases. There are interesting comic *phlyax* vases inspired by the popular theatre and the *vis comica*, characteristic of Tarentines of all periods. The magnificent gold and terra-cotta figurines surpass even those of Greece in delicacy and charm. Contrary to what written sources suggested, Taras unfortunately yielded very few statues. These are not all of Greek origin; some, the work of local artists or of Greeks adapting themselves to local requirements and temperament, seem animated by a clearly Italic realism. But, above all, the hundreds of reliefs in soft local stone are witness to the confident workmanship of skilled local craftsmen who, while conserving definite connections with the art of neighbouring Greece, present distinctive artistic tastes and tendencies.

Roman remains are better known. The remains of large public baths have been found along the Lungomare and near the church of S. Francesco. The ruins of an amphitheatre built of *opus reticulatum* (stone-faced concrete) lie beneath the present covered market; many scholars confuse this amphitheatre with the Greek theatre. Nothing is known of this theatre save that it was situated within view of the sea. Mosaic floors have been found in various places in the Città Nuova, and a whole house was discovered on the present site of the dry dock in the Arsenal. There are many cremation and burial tombs of the same period.

(AN. MO.; C. DR.; X.)

TARANTO PROVINCE, created in 1923, was known as the Province of the Ionian Sea from 1936 to 1951. Pop. (1961) 465,395, area 941 sq.mi. (2,436 sq.km.). It is for the most part mountainous, with deep gulfs and a narrow coastal plain. Helped by a mild climate, agriculture (cereals, vegetables, olives, and fruit; and stockbreeding are widespread, and there is important trade in grapes and Apulian wine. The principal centres are Massafra, divided by the picturesque ravine of San Marco; Grottaglie, which has an airport and is famous for its ceramic ware; Castellana Grotte, with its striking cathedral (rebuilt in 1400) and its bell tower; and Martina Franca (1,414 ft. [431 m.] above sea level), a summer resort, notable for its Baroque buildings. (M. T. A. N.)

**TARANTULA**, strictly speaking, a large spider (*Lycosa tarantula*) with a body about one inch long which takes its name from the town of Taranto in southern Italy. Its bite was formerly believed to be the cause of a disease known as tarantism. In this malady the victim wept, skipped about and then went into a wild dance (see TARANTELLA). Unless assisted by special music or magic antidotes, the victim was expected to die. Investigations have shown that the bite of this spider is not dangerous to man and that the disease attributed to it must have had other causes.

*Lycosa tarantula* belongs to the wolf spider family (*Lycosidae*) and has numerous allies in various parts of the world. The tarantula spins no web and catches its prey by pursuit. It inhabits dry, well-drained ground where it digs deep burrows. In the winter, the opening of the burrow is covered with silk, and the spider becomes dormant. It lives for several years.

BY COURTESY OF THE ZOOLOGICAL SOCIETY OF LONDON

A EUROPEAN LYCOSID TARANTULA

The name tarantula is often applied indiscriminately to large, fearsome hairy spiders of the suborder Mygalomorphae but is usually reserved for members of the family Theraphosidae, which are found in the southwestern United States, Mexico, and tropical America. Most of these forms are harmless to man, except for their nonpoisonous bite. Many of these spiders tunnel into the

soil, spending most of their life within this single burrow. They feed on large insects and occasionally on frogs, toads and mice.

In the southwestern United States, some tarantulas of the genus *Aphonopelma* attain a length of about 2 in. and a leg spread of from 4 to 5 in. These tarantulas are quite harmless and have been trained as pets; however, they can inflict painful wounds in self-defense. In South America, some tarantulas have a body length of more than 3 in. A few of these build huge webs and catch and kill large insects and even small birds for food.

See also SPIDER.

(C. J. Go.; M. L. G.)

**TARAPACÁ**, the northernmost province of Chile, bounded north by Peru, east by Bolivia, south by Antofagasta and west by the Pacific. Area 22,422 sq.mi. (58,073 sq.km.). Pop. (1960) 123,070. It is part of the Atacama desert (*q.v.*) region of the Pacific coast of South America and is without water except at the base of the Andes, where streams flow down into the sands and are lost. In some of these places there is vegetation and water enough to support small settlements.

The wealth of Tarapacá is in its immense deposits of nitrate of soda (found on the Pampa de Tamarugal, a broad desert plateau between the coast range and the Andes, which has an elevation of about 3,000 ft. [915 m.]). The mining and preparation of nitrate of soda for export has provided an uncertain livelihood for the population of this province. Silver is mined near Iquique (*q.v.*), the provincial capital. Unfavourable world markets for nitrate caused a decline in population after 1940. The principal ports of the province are Pisagua, Iquique and Arica (*q.v.*), from the first two of which "nitrate railways" run inland to the deposits.

Tarapacá was ceded to Chile by Peru after the war of 1879–83 and was organized as a province in 1884.

**TARASCO** (TARASCANS), the principal Indian group in the Mexican state of Michoacán, who term themselves and their language Purépecha. The expanding independent Tarascan nation at the time of the Spanish conquest dwindled until most Tarasco by the 20th century were confined to the pine- and oak-clad highlands dotted with volcanic cones and lakes west from Morelia and Lake Pátzcuaro and north from Uruapan and Parícutin volcano. Despite a culture that is more Old World than native, there is a marked retention of ethnic identity. During the 1960s there were approximately 60,000 persons of Purépecha speech, of whom perhaps one-fifth were monolingual. This language constitutes a linguistic family with no known relatives. Tarascan archaeology and history have been little studied, but artifacts and colonial accounts indicate that this group was the equal or superior of its Mexican contemporaries in the working of feathers, shell, wood, metal, and stone, and in military prowess; its architecture, however, was greatly inferior.

The Tarasco have no special tribal organization but participate in much the same political, economic, and religious organizations as do their neighbours of mixed ancestry. Agriculture is dominant; maize and wheat occupy most of the acreage, followed by pulses, cucurbits, barley, cabbage, and chili pepper. They also keep chickens, oxen, pigs, sheep, beehives, burros, and turkeys. In the mountain or sierra region forest products are quite important, and there the wooden house (*troje*) prevails. Among the leading cottage handicrafts are woodworking, pottery making, and weaving. Many Tarasco have gone as farm labourers (*braceros*) to the U.S., and most of the nearly 120 communities have at least one man who has lived in the U.S.

Among the leading communities are the Sierra capital Paracho, strongly Indian Cherán and Santa Fe, the Once Pueblos de la Cañada, and the sentimentally important former capitals Tzintzuntzan, Ihuatzio, and Pátzcuaro. In 1964–65 the Mexican government established a Tarascan regional coordinating centre in Cherán to develop schools, roads, hospitals, agriculture, and industry.

**TARASCON**, a town of southeastern France, in the *département* of Bouches-du-Rhône, 10½ mi. (17 km.) N of Arles. Pop. (1962) 6,475. It stands on the left bank of the Rhône opposite Beaucaire (*q.v.*), with which it is connected by railway and road bridges. Extensively damaged at the end of World War II, much of the town has been rebuilt, but the old quarters have kept their Provençal atmosphere with narrow streets, some still covered with inhabited archways. The Church of Sainte-Marthe is a historic monument. Of the Romanesque building (late 12th century) there remains chiefly the main porch flanked by richly ornamented columns. The church as a whole is Gothic (15th–16th centuries); its spire was destroyed in 1944 but was to be reconstructed. The crypt contains the tomb of St. Martha (the sister of Lazarus and the patron saint of the town) and that of Jean de Cossa (seneschal of Provence under King René), and also the Chapel of Saint-Lazare, built by Louis II, count of Provence. The château on a rock, falling steeply into the Rhône, from which Revolution prisoners were thrown into the river, was completed by René in the 15th century on the site of a Roman fortress. It has a courtyard, halls with painted pinewood ceilings, and two chapels, one above the other. Other notable buildings include the Hôtel de ville (1648), the Chapel of Notre Dame de Bonaventure (15th century), and the facade of the Benedictine Abbey (1358).

The town has manufactures of Provençal printed cloth and of paper pulp ("Rhône cellulose"), and a trade in fruit and early vegetables. In his novel *Tartarin de Tarascon* (1872), Alphonse Daudet satirized the life of the town and the southern character. The fête and procession are held on the last Sunday in June. The name of the town is associated with a legendary monster, La Tarasque, which was said to have ravaged the district and to have been tamed by St. Martha; its image figures in the town's coat of arms and in the procession. (J. E. G.)

**TARBERT**, a fishing village and summer resort at the head of East Loch Tarbert, an inlet of the sea on the western shore of the mouth of Loch Fyne, Argyll County, Scot., 38 mi. (61 km.) SSW of Inveraray by road. Pop. (1961) 1,313. The name (met elsewhere in Scotland) denotes an isthmus, and the village is in fact on the neck of land joining Kintyre to the rest of Argyll. This isthmus is little more than 1 mi. wide, and boats used to be dragged across to the head of West Loch Tarbert, a narrow sea loch nearly 10 mi. (16 km.) long. There is a good harbour with a pier for passenger steamers about ¼ mi. from the village. The herring fishery, though declined, is the main industry together with some shipbuilding. Overlooking the harbour are the ruins of a castle built by Robert I, "the Bruce," in 1326.

**TARBES**, a town and the *préfecture* in the *département* of Hautes-Pyrénées, France, 98 mi. (158 km.) WSW of Toulouse by rail. Pop. (1962) 46,162. It lies in the centre of a fertile plain below the Pyrenees, and on the left bank of the Adour River, streams from which are conducted through the town. The domed cathedral of Notre-Dame de la Sède dates from the 12th–14th centuries, and the largely restored churches of Saint-Jean and Sainte-Thérèse from the 14th and 15th centuries. The birthplace of Marshal Ferdinand Foch (1851–1929) is kept as a museum, and a street named after him is the commercial centre. In the Jardin Massey, a park donated by King Louis Philippe's gardener, is a bust of the poet Théophile Gautier (1811–72), who was born at Tarbes, and a museum of paintings and antiquities. The town was replanned in the 18th century with the help of Antoine Megret d'Étigny, intendant of Auch.

Tarbes is mentioned in the 5th century A.D. as the capital of the ancient province of Bigorre and the seat of a bishop. It was taken by the English in the Hundred Years' War and suffered considerable damage (1569) during the Wars of Religion. In 1814 Wellington gained a victory over the French under Marshal Soult near Tarbes. Until the mid-19th century it was important only as a market and an administrative centre, but the construction of the

railway from Morcenx in 1859 favoured the development of industry, and this was further encouraged by the establishment of an arsenal in 1872, after the Franco-German War. Between World Wars I and II the railways of the region were electrified, and important industries grew up near Tarbes, producing electrical and diesel equipment, and other machinery. Tarbes has also kept its importance as a market town for the surrounding agricultural district, and there is a stud for the breeding of Anglo-Arab horses. It is on the railway from Toulouse to Bayonne, and the airport 4 mi. (6½ km.) from the town serves Tarbes and Lourdes, which lies 12 mi. (19 km.) to the southwest. (CL. B.)

**TARDE, GABRIEL** (1843–1904), one of the most versatile and productive of French social scientists of his day, was born on March 12, 1843, at Sarlat, Dordogne. He served the French government as a provincial magistrate and as director of the Bureau of Criminal Statistics at the Ministry of Justice. In 1900 he was appointed professor of modern philosophy at the Collège de France. He died at Paris on May 13, 1904. The sequence of invention, repetition, conflict, and adaptation emphasized in Tarde's social philosophy seems to bear a close resemblance to Hegel's dialectic.

Tarde held that about one person in a hundred is inventive, yet that invention is the source of all progress. Inventions are imitated, but differ in degree and type of imitation, and this promotes opposition, both between varied limitations and between the new and the old in culture. The outcome of this opposition is an ultimate adaptation. This adaptation then becomes in itself an invention.

He saw this sequence as an unending cycle constituting the process of history and social experience (*Social Laws*, 1898). He treated repetition in his most famous work, *The Laws of Imitation* (1890); opposition in *Universal Opposition* (1897); and adaptation in *Social Logic* (1895). In *Comparative Criminality* (1886) and other works on criminology he attacked the extreme biological theories of C. Lombroso and his school, pointing out the environmental influences on behaviour. He also contributed to the studies of law and political science, crowd psychology and economics. His *Economic Psychology*, 2 vol. (1902), later stimulated J. A. Hobson in England and Thorstein Veblen and his followers in the United States. (H. E. BAR.)

**TARDIEU, ANDRÉ** (1876–1945), French statesman who attempted to carry on the policies of Georges Clemenceau in the aftermath of World War I. Born in Paris on Sept. 22, 1876, of an upper middle-class family, he studied at the École Normale Supérieure. After a period in the diplomatic service, he made his reputation as foreign editor of *Le Temps*. Elected to the Chamber of Deputies in 1914, he served with distinction in the Chasseurs-à-Pied during World War I till 1916. In 1917 he was sent on a special mission to the United States. At the Conference of Paris (q.v.), he had a considerable part in drafting the Treaty of Versailles. He was minister for the Liberated Areas (Alsace-Lorraine) in Clemenceau's government from November 1919 to January 1920. After Clemenceau's retirement he steadfastly refused to enter any government till 1926. In the Chamber and in the press he waged an uncompromising campaign against relaxation of the Treaty of Versailles. He lost his parliamentary seat in the elections of 1924 but recovered it in 1926. Then, to Clemenceau's chagrin, he accepted the ministry of public works and later the ministry of the interior under Raymond Poincaré. Leader of the right-centre in the Chamber, he was premier from Nov. 2, 1929, to Feb. 17, 1930, and again from March 2 to Dec. 5, 1930, advocating a policy of large national expenditure. He was minister of agriculture (1931–32) and of war (1932) in Pierre Laval's two cabinets before becoming premier for the third time on Feb. 20, 1932. Defeated in the general elections, he resigned on May 10, 1932. Finally, disgusted with the condition of public affairs, he retired from active politics in 1936. He died at Menton on Sept. 15, 1945.

Learned, witty, and self-assured, Tardieu wrote many books, including *La France et les alliances* (1908); *La Paix* (1921; English translation, *The Truth About the Treaty*); *Devant l'obstacle* (1927; English translation, *France and America*); and *La Révolu-*

*tion à refaire*, two volumes (1936–37), a denunciation of the French parliamentary system.

See G. Puaux et al., *André Tardieu* (1957).

(J. C. DE C.)

**TARDIGRADA**, a class of minute animals doubtfully placed among the arthropods (q.v.). The largest of the bear animalcules or water bears, as these animals have been commonly called, are not much more than 1 mm. in length, while most of them are very much smaller. They are free-living forms found in variable habitats, in damp moss, on flowering plants, in sand, fresh water and even in the sea; and in adaptation to this wide range of external conditions a large number of genera and species have been evolved.

The water bear has a well-developed head region and a short body composed of four fused segments, each represented externally by a pair of short, stout, unjointed limbs generally terminated by sharp claws, which seem to range in number from four to nine, but sometimes, as in *Batillipes*, ending in three pairs of racket-shaped, digitiform outgrowths. The limbs of the last pair project backward from the posterior end of the body on each side of the anus. The cuticle, which is not chitinated, may be smooth or sculptured in various ways and is sometimes strengthened with segmentally arranged plates (as in *Echiniscus*) and sometimes provided with long paired hairlike cirri. An interesting feature of the structure of Tardigrada is the more or less fixed number of cells of which their body is composed. Thus the median dorsal strip of epidermis is composed of only 24 pairs of cells.

No special organs of circulation or respiration are known. The alimentary canal traverses the body from end to end. Within the

FROM "CAMBRIDGE NATURAL HISTORY," BY PERMISSION OF THE MACMILLAN COMPANY, PUBLISHERS

ECHINISCUS SPINULOSUS, AFTER DOYÈRE

fore gut is a pair of protrusible stylets, large glands that open into the esophagus, a muscular pharynx and large median and lateral glands that open into the intestine posteriorly. The nervous system, which is remarkably well-developed, consists of a bilobate cerebral ganglion, frequently provided with a pair of eye-spots, and of a ventral chain

of five large ganglia connected by lateral commissures. The sexes are not distinct and the generative products are discharged either into the posterior end of the alimentary canal or directly to the exterior through a median pore in front of the anus. The eggs are large and in some cases at least are enclosed in the cuticle of the parent, which is cast to form a case for them. The young when hatched are about one-third the size of the parent, which they closely resemble except for the occasional absence of a pair of limbs that develop later.

The Tardigrada are divided into two orders: (1) the Heterotardigrada, containing two families with nine genera (*Echiniscus*, *Batillipes*, etc.), in which the head is provided with two pairs of cirri in front, a pair of lateral cirri and a so-called *clava* or spatulate process, one on each side; and (2) the Eutardigrada, containing two families and three genera (*Macrobiotus*, *Hypsibius* and *Milnesium*), in which cephalic cirri are wanting.

The most remarkable feature of the tardigrades is their ability to withstand desiccation and low temperature. Under unfavourable conditions, Tardigrades go into a state of suspended animation, or anabiosis. Specimens kept for eight days in a vacuum, transferred for three days into helium gas at room temperature, then exposed for several hours to a temperature of  $-272^{\circ}\text{C}$  came to life again when they were brought to normal room temperature; further, 60% of specimens kept for 21 months in liquid air at a temperature of  $-190^{\circ}\text{C}$  came to life. Specimens allowed to dry at room temperature and kept dry for 18 months returned to life in about two hours after having been transferred into water.

The Tardigrada cannot be assigned with complete confidence to the Arthropoda until it is proved that their oral stylets are modified appendages. Assuming that they belong to the Arthropoda, they must rank as a class by themselves. Some authors give Tardigrada phylum rank; a few scholars have suggested that the group is closer to Annelida.

**TARENTUM:** see TARANTO.

**TARGUL-MURES:** see TIRGU MURES.

**TARGUM.** The Targums are Aramaic translations—often interpretations or paraphrases—of the books of the Old Testament. In their earliest form they date from the time when Aramaic superseded Hebrew as the spoken language of large numbers of the Jews. (See HEBREW LANGUAGE; SEMITIC LANGUAGES.) In their origin they were designed to meet the needs of the unlearned among the people who had ceased to understand the Hebrew of the Old Testament. In the absence of any precise evidence on the point it is impossible to give more than a rough estimate as to the period at which Hebrew, as a spoken language, was generally displaced by Aramaic. It is certain, however, that Aramaic was firmly established in Palestine in the 1st century A.D., despite the fact that Hebrew still remained the learned and sacred tongue. Hence it may be reasonably inferred that the mass of the people had adopted Aramaic at a considerably earlier period, probably as early as the 2nd century B.C., and that the need of Aramaic translations of the sacred text made itself felt only a little later.

Just as the old Greek translation of the Pentateuch, the Septuagint (*q.v.*), came into being in Egypt about 200 B.C. to satisfy the needs of a Jewish population that increasingly favoured Greek over Hebrew as its vernacular, so, it appears, did the Targum on the Pentateuch appear at about the same time in western Asia—i.e., Babylonia and Judaea—where Aramaic had become the commonest vernacular tongue. At first the Pentateuch alone was involved, apparently because only the Law was as yet canonized as Sacred Scripture. In time, however, in the case of both the Septuagint and the Targums, the books of the Prophets and of the Hagiographa (Psalms, Proverbs, Job, Ruth, Lamentations of Jeremiah, Song of Solomon, Ecclesiastes, Esther, I and II Chronicles; for Ezra, Nehemiah and Daniel, however, no Targums have been found) were turned into Greek and Aramaic.

The status and influence of the Targums became assured after the Temple was destroyed, when synagogues replaced the Temple as houses of worship. For it was in the synagogue that the practice of reading from the Law and from the Prophets became widely observed, along with the custom of providing these readings with a translation into Aramaic.

This role of the Aramaic Targum became so generally recognized that by the 2nd century A.D. the Mishna (codification of the oral tradition, incorporated in the Talmud) takes it for granted and merely inculcates certain regulations to be observed by the *Meturgeman* ("translator"), who had by this time acquired a definite status. The Mishna indicates that the *Meturgeman*, who was distinct from the reader, translated each verse of the Law into Aramaic as soon as it had been read in Hebrew; in the readings from the Prophets three verses might be read at a time (*cf.* Luke iv, 16 ff.; Acts xiii, 14 ff., 27; xv, 21).

The translator endeavoured to reproduce the original as closely as possible, but, inasmuch as his object was to give an intelligible rendering, a merely literal translation would sometimes be insufficient; hence the translators tended to take a more elastic view of their obligations. To prevent misconceptions, they expanded and explained what was obscure, adjusted the incidents of the past to the ideas of later times, emphasized the moral lessons to be learned from the national history and, finally, adapted the rules and regulations of the Holy Scriptures to the conditions and requirements of their own age. As time went on, the practice of introducing additional matter of an edifying character grew in popular favour and was gradually extended. The method by which the text was thus utilized as a vehicle for conveying homiletic discourses, traditional sayings, legends and allegories is abundantly illustrated by the later Targums, as opposed to the more literal translations of the earlier Targum of Onkelos (*see below*) and on the Prophets.

It would be incorrect to suppose, however, that the translation of the text was left entirely to the individual taste of the trans-

lator. The latter is rather to be regarded as the representative of a school of thought reflecting the spirit of the age in which he lived.

There can be little doubt that the Targums existed for a long time in oral form, and so long at least as the Targum tradition remained active there would be little temptation to commit it to writing. But it is highly probable that this procedure, in the case of the Targums, was mainly followed with respect to those parts of the Old Testament which were read in the synagogical services (*e.g.*, the Law and the Prophets) and that it was less rigidly observed in regard to the other portions of Scripture; a written translation of the latter would be of special value for the purpose of private study. Hence there is no need to reject the tradition as to the existence of a written Targum on Job in the time of Gamaliel I (1st century A.D.), especially as references to Targum manuscripts occur in the Mishna and elsewhere. But it was not these manuscripts but the living tradition of the learned that was recognized as authoritative throughout the period that closes with the compilation of the Talmud in the early centuries of the Christian era. The official recognition of a written Targum, and therefore the final fixing of its text, belongs to the post-Talmudic period, and is not to be placed earlier than the 5th century A.D.

### TARGUMS ON THE PENTATEUCH

**Onkelos.**—The so-called Targum of Onkelos owes its name to a mistaken reference in the Babylonian Talmud. In its original context, that of the Jerusalem Talmud, the passage refers to the Greek translation of Aquila the proselyte. Onkelos the proselyte was mistakenly identified with him and then credited with the Aramaic translation of the Pentateuch. With the exception of this one reference, the Targum is always introduced in the Babylonian Talmud by the phrase "as we translate" or "our Targum"; it is probable, therefore, that the name of the author, or authors, was unknown to the Babylonian Jews. It is first quoted under the title of the Targum of Onkelos by the gaon Sar Shalom (d. c. A.D. 859).

The Targum of Onkelos may be regarded as an official translation of the Law, in the Judean Aramaic dialect, which was carried out in Babylon, probably about the 4th century A.D.; in its final form it cannot be earlier than the 5th century A.D. The translation, as a whole, is good, and adheres very closely to the Hebrew text.

Of all the extant Targums, that of Onkelos affords perhaps the most characteristic and consistent example of the exegetical methods employed in these works. Two principles may be said to have guided the translators. On the one hand, their primary object was to produce a faithful rendering of the original which at the same time would be intelligible to the people; for this purpose a purely literal translation would be insufficient. On the other hand, they regarded it as necessary to present the sacred text in such a manner as best to convey the particular form of interpretation then current. Later Jewish exegesis was especially concerned to eliminate everything in the sacred writings that might give rise to misconception with respect to God on the part of the unlearned.

Hence in the Targums various expedients were adopted for avoiding any reference to the Deity that might be misunderstood by the people or that involved apparent irreverence. Examples of this peculiarly Targumic method are: (1) the insertion of "word," "glory," or "presence" before the divine name, when God is referred to in his dealings with men; (2) the insertion of the preposition "before" when God is the object of any action; (3) the use of the passive for the active voice; (4) the use of periphrasis for the more pronounced anthropomorphisms, such as "to smell," "to taste"; (5) the use of different expressions or the insertion of a preposition before the divine name, when God is compared with man or the same action is predicated of God and man; (6) the use of distinctive terms "God" and "idol" where in the original the same characters are used to denote both God and heathen gods. Instances of this endeavour to maintain, as it were, a respectful distance in speaking of God occur on every page of the Targums;

at the same time, however, and by no means infrequently, less obviously physical human actions and passions are ascribed to God, a phenomenon that requires further study.

**Jerusalem Targums.**—Two other Targums to the Pentateuch are cited by Jewish authorities under the titles of the Targum Jerushalmi and the Targum of Jonathan ben Uzziel. Of these, the former contains only portions of the Pentateuch and is therefore usually designated the Fragmentary (Jerusalem) Targum.

The second Jerusalem Targum owes its ascription to Jonathan ben Uzziel to the incorrect solution (probably in the 14th century A.D.) of the abbreviated form by which it was frequently cited (viz., Targum Jerushalmi), hence the term "Pseudo-Jonathan" by which it often is designated. This Targum often represents a later and more successful attempt to correct and supplement the Targum of Onkelos by the aid of variants derived from an older source. It exhibits, also, that tendency to expand the text by additions of every kind that has been already noted as characteristic of the later stages of targumic composition. Homilies, legends, traditional sayings and explanations are utilized by the targumist, so that at times his works convey the impression more of a late exegetical work than of a translation.

It is not possible to determine the sources and dates of composition of these two Targums. It is generally agreed that, though the extant manuscripts are late, they preserve elements that go back to an early period. Most of these elements derive from the text tradition that gave rise to the Targum of Onkelos, yet others are independent of Onkelos.

We must assume that a tolerably fixed Targum tradition existed in Palestine from quite early times, and that the Targum of Onkelos was the main representative of this Targum tradition that existed among the Jews down to the 7th century A.D., the period to which the internal evidence compels us to assign the Targumim. (Cf. B. J. Roberts, *The Old Testament Text and Versions*, pp. 197-207 [1951].)

### TARGUMS ON THE PROPHETS

The official Targum on the Prophets is stated by the Babylonian Talmud to have been said by Jonathan ben Uzziel, the disciple of Hillel in Judaea, in the 1st century A.D., and is usually known, therefore, as the Targum Jonathan. Elsewhere in the Talmud, however, the quotations from this Targum are given under the name of Joseph bar Chijah, head of the school at Pumbeditha, in Babylonia, in the 4th century A.D. Both in language and style it closely resembles the Targum of Onkelos, and appears to have been modeled on that translation; in certain passages, indeed, it appears to have made use of it. Probably, like Onkelos, it did not assume its final form in Babylon before the 5th century A.D. It naturally follows from the character of the original that the rendering of this Targum is less literal than that of Onkelos, especially in the prophetic books, but, when due allowance is made for the difficulty of the Hebrew, it may be described on the whole as a faithful reproduction of the original text. Its peculiarities of rendering are a result of the same principles that were noted as underlying the translation of the Pentateuch.

Anthropomorphisms, as a rule, are avoided by means of the same expedients as those employed by Onkelos; expressions derogatory to the dignity of God, or of the heroes of the nation, are softened down; figurative language is either boldly transposed or its character clearly shown by introduction of the particle "as" or "like." There is, further, a tendency to interpret the prophetic utterances so as to make them applicable to the immediate enemies of the Jewish people. Lastly, in the obscurer passages the Haggadic method of interpretation (i.e., employing legend, folklore, homiletics, etc.) is employed to its fullest extent, while the translation throughout shows a marked tendency to explanatory additions.

Of a Jerusalem Targum to the Prophets little is known, though it is probable that such a Targum existed, if only in oral form.

### TARGUMS ON THE HAGIOGRAPHIA

These Targums are almost entirely the work of individuals, made in imitation of the older Targums.

**Psalms and Job.**—These Targums present certain features in common and may therefore be treated together. Like all the later Targums they exhibit a large amount of explanatory addition, chiefly Haggadic in character. At the same time the translation of the original is not neglected; and, when separated from the later accretions, this is found to follow the Hebrew fairly closely. Peculiar to these Targums are the double translations they give to many verses, one of which is usually Haggadic while the other is more literal. They cannot be earlier than the 7th century A.D. and possibly are of a considerably later date.

**Proverbs.**—This Targum stands apart because of the peculiarity of the language in which it is written. The influence of the Peshitta (Syriac) version of the Bible is so clearly marked that it has been described as a Jewish revision of that version. Setting aside the Syriacisms due to the use of the Peshitta, however, the Targum shows affinity to the Targums on the Psalms and Job. The translation is literal and almost entirely free from Haggadic additions.

**Megilloth.**—The chief characteristic of the Targums to the Megilloth (i.e., the latest books of the Hagiographa, namely the Song of Solomon, Ruth, Lamentations of Jeremiah, Ecclesiastes and Esther) is their exaggerated use of paraphrase. They mark the final stage in the development of Haggadic interpretation, in which the translation of the text has frequently disappeared in a mass of fanciful matter.

The Targum of Esther is known in three recensions: (1) that of the Antwerp Polyglot (late 16th century), almost a literal translation; (2) that of the London Polyglot (1657), which gives practically the same text with many additions of a Haggadic character; (3) the so-called second (*sheni*) Targum, a much larger work, containing a collection of later Midrashim ("explanatory commentaries") to this book.

The Targum on the Song of Solomon is of a similar character to that of the "second" Targum on Esther. These have been dated halfway between the Babylonian Targums (Onkelos and that to the Prophets) and the Jerusalem Targums on the Pentateuch and those on the greater Hagiographa.

**Chronicles.**—This Targum was first edited from an Erfurt manuscript in 1680-83; a more complete and accurate edition from a Cambridge manuscript was published in 1715. In the translation, which at times is fairly literal, use appears to have been made of the Jerusalem Targums on the Pentateuch and of the Targums on the books of Samuel and Kings. The text represented by the Erfurt manuscript is assigned to the 8th century, that of the Cambridge manuscript to the 9th century A.D.

(J. F. S.; H. M. O.)

**TARIFF**, a tax levied upon goods as they cross national boundaries, usually by the government of the importing country. The words tariff, duty, and customs are generally used interchangeably.

### NATURE AND FUNCTION OF TARIFFS

Tariffs may be levied either to raise revenue or to protect domestic industries, but a tariff designed primarily to raise revenue may exercise a strong protective influence and a tariff levied primarily for protection may yield revenue. Gottfried Haberler in his *Theory of International Trade* suggested that the best objective distinction between revenue duties and protective duties (disregarding the motives of the legislators) is to be found in their discriminatory effects as between domestic and foreign producers. If domestically produced goods bear the same taxation as similar imported goods, or if the goods subject to duty are not produced at home, even after the duty has been levied, and if there exist no home-produced substitutes toward which demand is diverted on account of the tariff, then the duty is not protective. A purely

protective duty tends to shift production away from the export industries into the protected domestic industries and those industries producing substitutes for which demand is increased. On the other hand, a purely revenue duty will not cause resources to be invested in industries producing the taxed goods or close substitutes for such goods, but it will divert resources from the production of export goods to the production of those goods and services upon which the additional government receipts are spent. From the purely revenue standpoint, a country will select a relatively small number of articles of general consumption and subject them to low duties so that there will be no tendency to shift resources into industries producing such taxed goods (or substitutes for them). During the period when it was on a free-trade basis, Great Britain followed this practice, levying low duties on a few commodities of general consumption such as tea, sugar, tobacco, and coffee. If a country wishes to protect its home industries its list of protected commodities will be long and the tariff rates high.

Tariffs may be further classified into three groups—transit duties, export duties, and import duties.

**Transit Duties.**—This type of duty is levied on commodities that originate in one country, cross another, and are consigned to a third. As the name implies, transit duties are levied by the country through which the goods pass. Such duties are no longer important instruments of commercial policy but during the mercantilist period (17th and 18th centuries) and even up to the middle of the 19th century in some countries, they played a role in directing trade and controlling certain of its routes. The development of the German *Zollverein* (customs union) in the first half of the 19th century was partly the result of Prussia's exercise of its power to levy transit duties. The most direct and immediate effect of transit duties is to reduce the amount of commodities traded internationally and raise their cost to the importing country. In 1921, the Barcelona Statute on Freedom of Transit abolished all transit duties.

**Export Duties.**—Export duties are no longer used to a great extent, but they were common in the past and were significant elements of mercantilist trade policies. Their main function was to safeguard domestic supplies rather than to raise revenue. Export duties were first introduced in England by a statute of 1275 that imposed them on hides and wool. By the middle of the 17th century the list of commodities subject to export duties had increased to include more than 200 articles. With the growth of free trade in the 19th century, export duties became less appealing; they were abolished in England in 1842, in France in 1857, and in Prussia in 1865. At the beginning of the 20th century only a few countries levied export duties: Spain still levied them on coke and textile waste; Bolivia and Malaya on tin; Italy on objects of art; and Rumania on hides and forest products. Export duties are generally levied by raw-material-producing countries rather than by advanced industrial countries. The neo-mercantilist revival in the 1920s and 1930s brought about the reappearance of export duties, but only to a limited extent. In the United States export duties were specifically prohibited by the Constitution. This prohibition was incorporated in the Constitution mainly because of pressure from the South, which wanted no restriction on its freedom to export agricultural products.

If the primary objective of the export duty is revenue, rates are usually low, for in the last analysis the duty is borne by the domestic producer, who cannot charge prices higher than the world prices. In South and Central America practically all exported commodities are taxed, the duties ranging from 1% to 5%. Several countries depend upon export duties for a large part of their revenue. Chile, for example, at one time derived more than 75% of her total revenue from export duties.

To the extent that export duties raise the cost of raw materials to foreign manufacturers relative to the cost to manufacturers in the exporting country, export duties may act as a form of protection to domestic industries. As examples, Norwegian and Swedish duties on exports of forest products were levied chiefly to encourage milling, woodworking, and paper manufacturing at home. Similarly duties on the export from India of untanned

hides after World War I were levied to stimulate the Indian tanning industry. In a number of cases, however, duties levied on exports from colonies were designed to protect the industries of the mother country and not those of the colony.

If the country imposing the export duty supplies only a small share of the world's exports and if competitive conditions prevail, the burden of an export duty will likely be borne by the domestic producer, who will receive the world price minus the duty and other charges. But if the country produces a significant fraction of the world output and if domestic supply is sensitive to lower net prices, then output will fall drastically and world prices may rise and as a consequence not only domestic producers but also foreign consumers will bear the export tax. How far a country can employ export duties to exploit its monopoly position in supplying certain raw materials depends upon the success other countries have in discovering substitutes or new sources of supply.

**Import Duties.**—Import duties are the most important and most common types of custom duties. As noted above, they may be levied either for revenue or protection or both, but tariffs are not a wholly satisfactory means of raising revenue, for tariff rates cannot be readily adjusted to current fiscal needs. In the United States, for example, revenues from import duties in 1808 amounted to twice the total of government expenditures, while in 1837 they were less than one third of such expenditures. Until near the end of the 19th century the customs receipts of the U.S. government made up about half of all its receipts. This share had fallen to about 6% of all receipts before the outbreak of World War II and by the 1960s was down to about 1½%.

A tariff may be either specific, ad valorem, or compound (*i.e.*, a combination of both). A specific duty is a levy of a given amount of money per unit of the import, such as \$1 per yard or per pound. An ad valorem duty, on the other hand, is calculated as a percentage of the value of the import. Ad valorem rates furnish a constant degree of protection at all levels of price (if prices change at the same rate at home and abroad), while the real burden of specific rates varies inversely with changes in the prices of the imports. A specific duty, however, penalizes more severely the lower grades of an imported commodity. This difficulty can be partly avoided by an elaborate and detailed classification of imports on the basis of the stage of finishing, but such a procedure makes for extremely long and complicated tariff schedules. Specific duties are easier to administer than ad valorem rates, for the latter often raise difficult administrative issues with respect to the valuation of imported articles.

A list of all import duties is usually known as a tariff schedule. A single tariff schedule, such as that of the United States, applies to all imports regardless of the country of origin. This is to say that a single duty is listed in the column opposite the enumerated commodities. A double-columned or multi-columned tariff provides for different rates according to the country of origin, lower rates being granted to commodities coming from countries with which tariff agreements have been negotiated. Most trade agreements are based on the most-favoured-nation clause, which extends to all nations whatever concessions are granted to the most-favoured nation. (*See MOST-FAVOURLED-NATION TREATMENT.*)

Every country has a free list that includes articles admitted without duty. By looking at the free list and the value of the goods imported into the United States under it one might be led to conclude that tariff protection is very limited, for more than half of all imports are exempt from duties. Such a conclusion, however, is not correct, for it ignores the fact that the higher the tariff, the less will be the quantity of dutiable imports. Attempts to measure the height of a tariff wall and make international comparisons of the degree of protection, based upon the ratio of tariff receipts to the total value of imports, are beset by difficulties and have little meaning. A better method of measuring the height of a tariff wall is to convert all duties into ad valorem figures and then estimate the weighted-average rate. The weight should reflect the relative importance of the different imports; a tariff on foodstuffs, for example, may be far more important than a tariff on luxuries consumed by a small group of people. A tariff index may be used to measure either the degree of protection afforded

by a tariff schedule or the relative degree of import obstruction that it provides. If the amount of protection is under consideration, then it must be recognized that even a uniform ad valorem rate of duty will provide different protection to different countries, depending in part upon demand and cost differences between countries. The degree of obstruction to imports, on the other hand, would depend not only upon the height of the tariff but also upon the responsiveness of demand and supply, the changes of which are not considered in computing the tariff index. Consequently, it is misleading to construct only one tariff index for a given country. For each country a number of tariff indexes should be computed, one for each country from which it imports, for it often happens that a tariff severely restricts imports from certain countries but has little effect on imports from other countries.

### TARIFFS IN THE 20TH CENTURY

Viewing the development of tariffs and international trade since 1900, three broad periods can be distinguished: (1) from 1900 to World War I, (2) from 1919 to World War II, and (3) from World War II to the 1960s. During the first period tariffs were the main form of import control. They were moderate and relatively stable, and equality of competitive opportunity for imports from all countries was the rule, with exceptions found mainly in the trade relations between a few countries and their colonies.

The second period, from 1919 to 1939, was marked by frequent changes in duties, their rise to a higher level, the development of new control devices, and the negotiation of special trade agreements. There was some resurgence of protective tariffs immediately after World War I, caused in part by the strong national feelings aroused by the war and by difficult postwar economic adjustments. As political and economic conditions improved toward the middle of the 1920s the severity of trade restrictions was relaxed. In the late 1920s many governments negotiated commercial treaties that resulted in mutual reductions in duties. Soon after the beginning of the depression of the 1930s, however, this liberal trend was reversed. Import controls and higher tariffs were adopted by one country after another. Two outstanding examples of such legislation were the Smoot-Hawley Tariff (1930) in the United States and the British tariff of 1932 that ended nearly a century of virtual free trade for Great Britain. The world economic conference that convened in London in 1933 to deal with tariffs and international trade failed because it came too late to supersede the various national recovery programs that had already gained momentum in many countries, particularly the United States. Despite the moderating influence of the U.S. Reciprocal Trade Agreements Act (1934), which was designed to reduce tariffs and stimulate trade, the dominant trend in the trade policies of most countries during the 1930s was in the opposite direction; no effective methods of concerted action were devised for checking the deterioration of the economic relations among nations.

The third period, from World War II to the 1960s, brought radical changes in the nature and control of world trade. During the war the shortage of many types of goods for ordinary civilian use, and of the shipping to carry them, limited the volume of ordinary trade. Under these circumstances, tariffs and other means of control became subordinate to the decisions of the exporting countries as to whether the particular goods could be spared and as to whether transport was available to carry them. To a large extent, governments themselves participated in the procurement and distribution of many classes of goods. As the war progressed, the enlarged production programs of the Allies and of the countries friendly to them resulted in huge international movements of supplies. The problem of paying for these goods was virtually eliminated by the U.S. Lend-Lease Act, which authorized the president to make them available to friendly countries on a lend-lease basis, *i.e.*, without immediate compensation. A significant feature of the agreements concluded by the United States with more than 30 of the United Nations was the uniform pledge of all the contracting countries to collaborate after the war in a program designed to promote more liberal conditions for international trading and a more prosperous expanding world economy.

Soon after the war the United States and Canada, in order to

facilitate the resumption of normal trade, relaxed their controls upon exports and extended loans to many other countries. Western European countries negotiated numerous trade agreements with each other. Unlike their predecessors of the prewar era, these agreements did not deal with changes in tariffs or other trade controls. The negotiations centred rather upon the lists of goods that each country was desirous of obtaining from the other and the delivery of which the other government agreed to facilitate. Generally speaking, even after the transitional period following World War II, the course of international trade was determined only to a small degree by the height of the tariff or by licensing systems. The main determinants were the needs of the war-torn areas for products essential to the rehabilitation of their economies.

By the close of 1947, new or tightened import restrictions had been brought into operation by various countries to prevent further loss of foreign exchange. These restrictions were directed chiefly against imports from the dollar countries of North and South America. To ease the settlement of uneven balances in the trade among the European countries themselves, a special intra-European payments plan was inaugurated in 1948. Under this arrangement portions of the dollar aid allocated through the Marshall Plan to European countries were made conditional upon the setting up by these countries of special accounts of equivalent value in their own currencies, against which members with whom they had an export surplus could draw to finance their deficits. This was later replaced by a flexible system for clearing balances, known as the European Payments Union (*q.v.*).

The progressive improvement in production, monetary stability, and trade balance which many countries were making gave promise, by the beginning of 1950, of some trade normalization. Early in 1950 the western European countries that had received Marshall Plan aid agreed upon a series of steps for the liberalization of import quotas. Later, smaller groups of countries formed customs unions such as the Benelux customs union, the European Economic Community (Common Market), the European Free Trade Association (EFTA), and the Latin American Free Trade Association. (See *ECONOMIC UNION*.) On the other hand, in the major countries of Asia, progress toward resumption of normal trade relations was still largely dependent upon political developments. Among the factors hampering trade in Asia were the Communist control of China and the continued disturbances in Southeast Asia. On the favourable side were the stabilization of the Japanese yen and the transfer of Japanese trade to private channels.

**General Agreement on Tariffs and Trade.**—The most important expression of the postwar desire of the nations of the world to liberalize and expand international trade was the General Agreement on Tariffs and Trade (GATT). It consisted of an integrated set of bilateral trade agreements (negotiated in five international conferences) aimed at the abolition of quantitative trade restrictions and the reduction of tariff duties among the contracting parties. GATT was concluded at Geneva, Switz., in 1947 and was originally considered as an interim measure pending the formation of a United Nations agency to supersede it. For this latter purpose the United Nations Economic and Social Council called an international conference on trade and employment that met in Havana, Cuba, from November 1947 to March 1948 to draw up the charter of an agency to be known as the International Trade Organization (ITO). The ITO was designed to support national policies for economic development and full employment and contribute to the gradual liberalization of world trade. Simultaneously the members of the preparatory committee of the ITO charter met in Geneva and negotiated the General Agreement on Tariffs and Trade. Of the 56 nations represented at Havana, 53 signed the proposed ITO charter, but only one subsequently ratified it, and plans for ITO were therefore abandoned. Since the ITO did not come into being, GATT was amplified and further enlarged at Annecy, Fr., in 1949, at Torquay, Eng., in 1951, and at Geneva in 1956 and 1961. A new conference for further negotiations, known as the "Kennedy round" (in honour of Pres. John F. Kennedy, during whose term the U.S. Trade Expansion Act of 1962 was passed), formally opened in Geneva in May 1964 and was continued in 1965.

GATT includes a long schedule of specific tariff concessions for each contracting party, representing tariff rates which each country has agreed to extend to others. In addition it includes a set of general rules for the conduct of international trade; these rules are, in effect, a code of commercial policy. They provide for unconditional most-favoured-nation clauses, elimination of quantitative trade restrictions, uniform customs regulations, and the obligation of each contracting party to negotiate for tariff cuts upon the request of another. The negotiating procedures followed under GATT agreements are essentially multilateral. The close contacts among the country representatives who attend the negotiating sessions, and the fact that each country is affected not only by its bilateral negotiations but also by the negotiations under way among other pairs of countries, make GATT negotiations in effect multilateral.

By 1965 the membership of GATT included 64 countries, which accounted for more than four-fifths of all world trade. Trade negotiations under GATT covered scores of thousands of commodities. Tariff concessions were granted on about two-thirds of the total imports of all GATT countries.

For current developments in tariff negotiations see *Britannica Book of the Year*. See also **FREE TRADE**; **TRADE, INTERNATIONAL**; and references under "Tariffs" in the Index.

**TARIJA**, a department of southeastern Bolivia established in 1832 during the administration of Andrés de Santa Cruz. Area 14,526 sq.mi., pop. (1962 est.) 142,600. It is bounded south by Argentina, east by Paraguay, and west and north by the departments of Potosí and Chuquisaca. The plains provide excellent grazing lands for breeding horses, cattle, and sheep. Corn, wheat, fruits, and vegetables are grown. The eastern tropical region in the Chaco (q.v.) lowland produces tobacco, sugarcane, rice, bananas, cassava, and citrus. Mineral resources include petroleum, iron, and silver. Oil refineries are at Sanandita and Fortín Campero.

Tarija, the departmental capital (pop. [1962 est.] 20,851), in a small valley on the banks of the Río Grande de Tarija, was founded by Don Luis de Fuentes y Vargas in 1574. Its elevation, 6,250 ft., helps temper the climate. (J. L. Tr.)

**TARIM**, the chief river of Sinkiang province, China, which gives its name to the great basin between the Tien Shan and Kunlun mountain systems of central Asia. It is 1,360 mi. (2,190 km.) long, and the area of the basin is approximately 300,000 sq.mi. (777,000 sq.km.), though another 50,000 sq.mi. (129,500 sq.km.) portion of the southwest Gobi desert sometimes is included with the Tarim basin.

The Tarim river is formed by the confluence of the Kizil (Kashgar) and the Yarkand rivers in the far west; it then flows for about 230 mi. (370 km.) NE, to be joined from the north by the Ak Su and shortly, from the south, by the Khotan, though the latter only reaches the Tarim for a period of about 40 days per year. Trending eastward, along the northern side of the Takla Makan desert, the Tarim divides repeatedly and has inter-dune lakes along its course. The Konche, issuing from the lake called Baghrash Köl, joins the Tarim just eastward of long. 88° E. The lower course of the Tarim is sluggish, diminishing in volume, and is aggrading its bed. In 1921 it broke out of its channel and returned to an old course followed before A.D. 330, also moving the marshy Lop Nor back to its classical location. The river is usually frozen from December through February. The March thaw causes inundations, followed by a great summer flood as the snows melt in the Tien Shan and the Kunlun.

The basin properly consists of three regional divisions, though sometimes five units are distinguished. The first division is the Takla Makan desert or central, waterless sand desert. The terminal depression of Lop Nor is the second division, which often

is considered a part of the Takla Makan. Its salt-encrusted dry lake beds, old river channels and changeable marshy lake terminals of the Tarim seldom have permitted permanent occupancy. The third division comprises the belts of oases surrounding the Takla Makan on the south, west and north along the piedmont fringes north of the Kunlun, east of the Pamir and south of the Tien Shan. These oases lie between the gravel glacis of the upper piedmonts and the sands of the Takla Makan. The best-known oases on the south are Karghalik, Khotan, Keriya, Niya, Cherchen and Charkhlik. To the west are Yarkand and Kashgar. On the north are Wu-shih, Ak Su, Bai, Kuchche, Korlo and Karashahr. The southern oases have smaller water supplies and cultivable areas than those of the north, but the western oases are the largest. The two other regional units often included in the Tarim, for convenience, are: the Turfan depression, lying beyond the Kuruk Tagh to the northeast in the indeterminate zone between the Tarim basin and the Gobi country; and the Su-lo (Shuleh) basin at the western end of the Kansu corridor, north of the Nan Shan.

**Problems of Climatic History.**—The present-day climate of the Tarim basin is discussed in the article **SINKIANG**, but the problems of past climatic changes have been the subject of much study. In general the belief has increased that climate has not changed markedly since the end of the last glacial era, but that the water supplied by the melting of glacial ice left in the high mountains has been failing. The problem is connected with the supposed desiccation of central Asia. (See **ASIA: Exploration**.)

Regardless of cause, great changes have occurred in the Tarim basin during the last 2,500 years. Settlements away from the piedmont were abandoned, sometimes to be replaced by smaller settlements higher on the piedmont edge. Some localities formerly well watered and prosperous now are deserted and quite uninhabitable. Many streams no longer penetrate the desert fringe, and the Tarim has shifted its course repeatedly, to alter the route of the Silk road.

**Historical Geography.**—The chief old land route of contact between eastern and western Asia passed through the Tarim basin. A northern route along the southern foot of the Tien Shan connected the trans-Caspian lowlands, via Kashgar and the Pamir passes, with the Kansu corridor in the east; a southern route along the northern Kunlun piedmont made the same connections. The region was always essentially a corridor zone, since there never was sufficient moisture, widely distributed, to support extensive plant, animal or human life. This explains why the great nomadic tribes of Dzungaria, the Wu-sun, Sakas, Yue-chi, Huns, Turks and Mongols raided or made tributary the Tarim oases, but never permanently crossed the Tien Shan to occupy the basin. Yet the oases provided the resource for careful irrigation agriculture to small groups of people, and provided food, animals and water for small numbers of migrants, travelers and traders.

**Modern Conditions in the Tarim Basin.**—Basically, the Tarim is yet untouched by modern developments, either of mineral resources or of water conservation-irrigation systems. Chinese administration, in times of strong Chinese power, has kept the routes open and free from banditry, but during the 19th century such periods were short. The oases populations chiefly are Turkic peoples, unsympathetic to the Chinese, but neither sufficiently numerous nor united to develop their regional entity. The Chinese fear of foreign exploitation has prevented both full exploration of possibilities and the development of known resources. The lack of transport development has kept connections uncertain and movement both slow and costly. The Tarim has lain too far from the centre of any modern regional development to have shared in that growth. The Communist Chinese have plans for marked development of several localities of the basin, but the comparatively small opportunities make them of relatively low priority and, by the 1960s, little was achieved other than the political organization of the region and the settling of Chinese nuclei in most of the important oases. A few agricultural processing plants were established, and resource exploration begun.

Oasis agriculture remains the mainstay of the scattered settlements. Grains, cotton, silk, fruits and wool are the chief agricultural products, and Khotan jades are the only other important item. Little is exported from the basin, but local surpluses find a

market among travelers passing through when conditions permit. See also SINKIANG; KASHGAR; KHOTAN; YARKAND RIVER; LOP NOR; GOBI; TAKLA MAKAN; DZUNGARIA. (J. E. SR.)

**TARKINGTON, (NEWTON) BOOTH** (1869-1946), U.S. novelist and dramatist whose satirical pictures of midwesterners represent his best work, was born in Indianapolis, Ind., July 29, 1869. He studied at Phillips Exeter Academy, Exeter, N.H., and at Purdue (West Lafayette, Ind.) and Princeton universities. In 1902-03 he was a Republican member of the Indiana legislature. A versatile and prolific writer, Tarkington won early recognition with the melodramatic novel *The Gentleman from Indiana* (1899). This was followed by the immensely popular romance *Monsieur Beaucaire* (1900), which he later adapted for the stage. *The Conquest of Canaan* (1905), a "problem" novel, was probably the most mature work of his early period. His humorous portrayals of boyhood and adolescence, *Penrod* (1914) and *Seventeen* (1916), became classics of their kind. He was equally successful with his portrayals of midwestern life and character: *The Turmoil* (1915), *The Magnificent Ambersons* (1918; Pulitzer Prize, fiction, 1919) and *The Midlander* (1924), combined as *Growth* (1927); and *The Plutocrat* (1927). *Alice Adams* (1921; Pulitzer Prize, fiction, 1922), a searching character study, is perhaps his most finished novel. He continued his celebrated delineations of feminine character in *Claire Ambler* (1928), *Mirthful Haven* (1930), and *Presenting Lily Mars* (1933), and wrote several domestic novels in his later years. His many plays include *The Man from Home* (1908), *Mister Antonio* (1916) and *Up from Nowhere* (1919), all with H. L. Wilson, and *Beauty and the Jacobin* (1912). He died on May 19, 1946, in Indianapolis.

Adopting William Dean Howells and Mark Twain as his literary models, Tarkington possessed an informal, charming style and a gift for characterization. However, sentiment often obscured his critical vision.

**BIBLIOGRAPHY.**—R. C. Holliday, *Booth Tarkington* (1918); James Woodress, *Booth Tarkington, Gentleman from Indiana* (1955); D. Russo and T. Sullivan, *A Bibliography of Booth Tarkington* (1949).

**TARLAC**, an agricultural province on the central plain of Luzon, Republic of the Philippines, in the region drained by the Agno River. Area 1,175 sq.mi. (3,043 sq.km.); pop. (1960) 426,647. Soils are of alluvial origin and range from sandy loams, through clay loams, to clays. In many areas the subsoil is a tight clay. Rice is the principal crop and in a part of the province two crops per year are possible, the second by means of controlled irrigation. Sugarcane is the second crop, and one of the most modern sugar centrals in the republic is at San Miguel, near the centre of the province. Other crops are corn, beans, tobacco, sweet potatoes, and coconuts. Pampango is the principal vernacular, but Tagalog, Ilocano, and Pangasinan are also spoken. With considerable absentee ownership, this was an area where the Hukbalahap movement was quite strong. (See PHILIPPINES, REPUBLIC OF THE.)

**TARLAC MUNICIPALITY** (pop. [1960] 98,285), the provincial capital, was founded in 1686 and lies on the railway and paved highway from Manila to northern Luzon. (AN. C.)

**TARN**, a *département* of southwestern France, formed in 1790 from the three dioceses of Albi, Castres, and Lavaur in the western part of Languedoc (q.v.). It is bounded north and northeast by Aveyron *département*, southeast by Hérault, south by Aude, southwest by Haute-Garonne, and northwest by Tarn-et-Garonne, and is included in the economic region of Midi-Pyrénées, established in 1964. Area 2,220 sq.mi. (5,751 sq.km.). Pop. (1962) 319,560. Extending northward from the Montagne Noire (the southwesternmost spur of the Massif Central), it lies across the margin of the crystalline highlands and the lowlands of Aquitaine and is drained westward by tributaries of the Garonne River, including the Aveyron (which marks its northern limit), Tarn, and Agout. The granite country in the east forms exposed tracts of undulating plateau above 2,000 ft. (600 m.), with the highest parts, in the Montagne Noire, reaching 3,970 ft. (1,210 m.). The inclement climate and poor acid soils restrict farming. The traditional crops (rye and chestnut) of the former subsistence economy have given way to grass and fodder crops, and the highlands are now concerned

mainly with rearing cattle and sheep. Lead and zinc ores in the crystalline rocks are worked on a small scale at Peyrebrune. Farther west, in Albigeois pays, are lower limestone plateaus, about 600-800 ft. (180-250 m.) above sea level, trenched by the valleys of the Aveyron, Tarn, and Agout, which open onto marl lowlands. The lowlands and their valley extensions support a rich agriculture with wheat, maize (corn), vineyards, orchards, and also lush meadows on the valley floors. The sparkling wine of Gaillac is of high repute. At Castres and Mazamet, market towns at the foot of the Montagne Noire, old woolen industries survive. North of Albi (q.v.) there is a small coalfield around Carmaux. With its development and the coming of the railway in the mid-19th century Albi experienced industrial growth. Although there is an important post-World War II coking plant at Carmaux, much of the coal output is sent away, and for its industries (chiefly engineering, and the manufacture of glass, cement, detergents, and synthetic fibres) Albi relies mainly upon waterpower, generated from the Tarn at its passage from the crystalline rocks above the town. Situated at an important crossing of the Tarn near the margin of the highlands, Albi is the largest town and *préfecture* and is an old-established cathedral city, centre of an archbishopric. Its medieval brick bridge lies between the modern road and railway crossings of the Tarn. The fortified cathedral of Sainte-Cécile, the crowning glory of southern Gothic architecture, towers above the city. The archiepiscopal fortress, Palais de la Berbie, alongside, now houses the Toulouse-Lautrec Museum. At Lavaur the church of Saint-Aignan, a former cathedral, is another fine example of southern Gothic. The Goya Museum at Castres has a notable collection of Spanish art. Tarn is divided into two *arrondissements* centred upon Albi and Castres. It comes under the jurisdiction of the Court of Appeal at Toulouse and under the *académie* there for the administration of education. (AR. E. S.)

**TARN-ET-GARONNE**, a *département* of southwestern France, formed by a reorganization in 1808 of districts that before the Revolution had belonged to the historic regions of Guenne and Gascony (qq.v.), and the addition of a small portion of Languedoc. It is bounded north by Lot *département*, east by Aveyron and Tarn, south by Haute-Garonne, and west by Gers and Lot-et-Garonne, and is included in the economic region of Midi-Pyrénées established in 1964. Area 1,435 sq.mi. (3,716 sq.km.). Pop. (1962) 175,847. It consists of lowland country in the clayey *molasse* tracts of the Aquitaine Basin, around the confluence of the Tarn and Aveyron rivers and of the joint stream with the Garonne. The mild climate and fertile soils make it a productive agricultural district, but it lacks mineral wealth and has little industry, though rubber manufacture has developed since World War II at Moissac. Wheat and maize (corn) are extensively grown, vineyards and orchards are also widespread, and cattle are fattened or kept for dairying. The lateral canal of the Garonne traverses the *département*, with a spur serving Montauban (q.v.) which is an important focus of roads and railways. Montauban has a fine medieval brick bridge across the Tarn; it is the largest town and the *préfecture* and is the centre of the diocese that is coextensive with the *département*. Montauban and Castelsarrasin are the centres of the two *arrondissements* into which Tarn-et-Garonne is divided. The *département* comes under the jurisdiction of the Court of Appeal at Toulouse and under the *académie* there for the administration of education. (AR. E. S.)

**TARNOW**, a town in Cracow (Krakow) *województwo*, Poland, and seat of a Roman Catholic bishopric, lies 45 mi. (72 km.) E of Cracow and is a rail junction on the Cracow-Lvov, U.S.S.R., line. Pop. (1960) 70,835. Tarnow is situated on the borders of the Carpathians and the Sandomierz Plain, near the confluence of the Biala River with the Dunajec, a tributary of the Vistula. Its industries comprise mainly chemical, machinery, electro-technical and ceramic works. It is mentioned as a settlement in the 12th century. It prospered under the protection of its owners, the Tarnowski family, and a branch of the Cracow Academy of Sciences was established there in the 16th century. It was seized by Austria after the first partition of Poland, in 1772. The tombs in the cathedral are among the finest Renaissance treasures in Poland. There are two museums. (T. K. W.)

**TARNOWSKI, JAN**, COUNT (1488–1561), Polish army commander, the mainstay of authority against the *szlachta*, or petty nobles. He was born at the Tarnow castle, of a magnate family. He fought well in southeastern Poland against Bogdan III of Moldavia (1509), at Wisniewiec against the Tatars (1512), and at Orsza against the Muscovites (1514). In 1517 he left Poland for travels in the Near East and in western Europe. In Portugal in 1520 he commanded an army against the Moors. Returning to Poland in 1521, he served against the Teutonic Knights.

In 1527 King Sigismund I appointed Tarnowski grand hetman (commander in chief of the army) and governor of the Lwow-Halicz province. Tarnowski won a great victory over the Moldavians at Obertyn in 1531 and commanded against Muscovy in 1535. He did much to bring immigrants to southeastern Poland. He was appointed governor of the Cracow province in 1535 and castellan of Cracow itself in 1536. He took the king's side during the "Poultry War" of 1536, a bloodless revolt of the *szlachta* against efforts to increase the royal power. Advocating a pro-Habsburg policy, Tarnowski in 1544 organized a private raid against Ochakov, a Turkish fortress on the Black Sea.

In 1548 Tarnowski sided with Sigismund II Augustus when the *szlachta* tried to annul the latter's marriage with Barbara Radziwill. A devout Catholic, he yet opposed the restoration of independent episcopal courts. He wrote *De bello cum . . . Turcis gerendo* (1552), for Charles V's projected war against the Turks, and *Consilium rationis bellicae* (1558), on traditional Polish methods of warfare. He died at Tarnow on May 16, 1561. (St. HE.)

**TARN RIVER**, in southwestern France, 233 mi. (375 km.) long, enters the Garonne below Moissac. It rises above 5,000 ft. (1,500 m.) on the Lozère plateau in the Massif Central and flows west to enter its great gorge, between 1,300 and 1,700 ft. (400–500 m.) deep, across the limestone Causses plateaus between Florac and Millau. Its tributaries, the Jonte and Dourbie, flow in similar gorges between walls of white limestone. The gorges present an important tourist attraction. Below the small verdant basin of Millau, the Tarn is again trenched in the crystalline plateaus of the southwest part of the Massif Central, but near Albi the valley opens out in the fertile agricultural lowlands of Aquitaine. Below the confluence of the Agout, the Tarn turns northwest in a course nearly parallel with the Garonne but does not bend west toward that river until, some distance below Montauban, it has received an important tributary, the Aveyron. (Ar. E. S.)

**TARO** (*Colocasia antiquorum*), a coarse herbaceous plant of the arum family (Araceae; *q.v.*), called also eddo, probably native to southeastern Asia, whence it has spread to the Pacific Islands, where it is extensively cultivated for its large, spherical, underground tubers, rich in starch; these form an important article of food, especially in Hawaii. The Polynesian poi is a thin pasty mass of taro starch.

It is closely allied to the dasheen (*C. esculenta*), native to Indonesia, various cultivated forms of which are known as elephant's-ear. The dasheen tubers have a nutty flavour and contain more carbohydrates and proteins than the potato.

**TAROT**, a game of cards played in Germany (*tarok*) and central Europe and to some extent in France and Italy (*tarocchi*) (see CARDS, PLAYING). The modern game uses 54 cards, comprising 32 suit cards, 21 tarots (permanent trumps), and a joker. Each suit includes 4 court cards, instead of 3 as in the 52-card French pack. The tarots, originally illuminated with individual designs of esoteric significance, now are usually printed only with the Roman numerals from I to XXI. The play of the game centres upon the manipulation of the tarots, each of which is privileged to win any suit card. Tarot includes many features that were borrowed by other games—competitive bidding, a scat or widow, melding of honour combinations, the sequence of matadors, the suitless or wild joker, the effort to capture specific counting cards in tricks, and extra score for the last trick.

**TARPEIA**, in Roman legend, daughter of the commander of the Capitol during the war with the Sabines caused by the rape of the Sabine women. According to the story, she offered to betray the citadel if the Sabines would give her what they wore on their left arms, meaning their bracelets; instead of this, keeping to the

letter of their promise, they threw their shields upon her and crushed her to death. Simylus, a Greek elegiac poet, makes Tarpeia betray the Capitol to a king of the Gauls.

The story may be an attempt to account for the Tarpeian Rock, on the southwestern corner of the Capitoline Hill, being chosen as the place of execution of traitors. According to S. Reinach, however, the story had its origin in a rite—the taboo of military spoils, which led to their being heaped up on consecrated ground that they might not be touched. Tarpeia herself is a local divinity, the manner of whose death was suggested by the tumulus or shields on the spot devoted to her cult, a crime being invented to account for the supposed punishment. (R. B. Ld.)

**TARPON**, a marine fish closely allied to the herring, identified by a filamentous prolongation of the last dorsal fin ray, by the dorsal fin originating behind the ventrals, and by a bony plate on the throat between the two sides of the lower jaw. The body is covered with large, thick, silvery scales. Two species are known. The Atlantic tarpon (*Megalops atlantica*) occurs in tropical and subtropical parts of the western Atlantic from Brazil northward, occasionally as far as Nova Scotia; on the west coast of Africa; and, as a result of passage through the Panama Canal, on the Pacific side of Central America. It lives close inshore, often in semi-enclosed bodies of water, and in rivers sometimes 100 mi. or more from the sea. It evidently spawns in shallow water along shore during spring and summer. Tarpon have the habit of breaking the surface of the water and gulping air, the lunglike swim bladder functioning as an accessory respiratory organ. It is a favourite big game fish. The Indo-Pacific tarpon (*Megalops cyprinoides*) occurs around the shores of the Indian Ocean from as far south as Durban, South Africa, into the Pacific to Formosa and about as far east as the Society Islands. (L. A. Wd.)

**TARQUIN** (TARQUINIUS), the name of two kings of Rome. LUCIUS TARQUINIUS PRISCUS, fifth king (traditionally 616–578 B.C.), was said to be the son of a Greek, Demaratus of Corinth, who came to live in Tarquinii in Etruria. The son in turn, originally named Lucumo, moved to Rome on the advice of his wife, the prophetess Tanaquil (*q.v.*). Changing his name to Lucius Tarquinius, he came to be appointed guardian to the sons of the king Ancus Marcius and finally supplanted them upon their father's death. Eventually he was assassinated at the instigation of Ancus' sons.

Tarquinius Priscus was said to have increased the Senate by the addition of 100 junior members and to have doubled the number of knights (*equites*). More authentic is his building program: he laid out the Circus Maximus, instituted the Roman Games (*Ludi Romani*), built the great sewer (*Cloaca Maxima*), and began construction of a wall around the city and the Temple of Jupiter Optimus Maximus on the Capitol. He carried on war successfully against the Sabines and subjugated Latium.

LUCIUS TARQUINIUS SUPERBUS, seventh and last king (traditionally 534–510 B.C.), is in legend the son (or grandson) of Tarquinius Priscus and son-in-law of Servius Tullius (*q.v.*), the sixth king. He came to power by murdering his predecessor and set up an absolute despotism (hence his name Superbus, "the proud"). A reign of terror followed during which many senators were put to death. Eventually a revolt was instigated by the leading senators, immediate cause for which was the rape of Lucretia (*q.v.*) by Superbus' son Sextus. This resulted in the expulsion of the Tarquins and the end of the monarchy. Tarquinius' efforts to force his way back to the throne were in vain (see PORSENA, LARS) and he died in exile.

Although many of the details of their careers are clearly fictitious, they are probably both historical personages. Some modern authorities, however, believe that a single figure (or else a series of Etruscan kings) is behind the two legendary Tarquins. That they came from Etruria is confirmed by both Roman and Etruscan legend and has the strong support of archaeological evidence, for their presence in Rome coincides with a period of roughly 100 years of Etruscan influence in the city preceding the foundation of the republic.

That the monarchy was overthrown is historical fact, and the existence of at least one Tarquin cannot be questioned. Their

successful wars with the Latins also must be regarded as fact. The text of a treaty between Tarquinius (Superbus?) and Gabii was preserved in the Temple of Semo Sancus in Rome as late as the time of Augustus. The foundation of the Temple of Jupiter on the Capitoline Hill, from both architectural and religious evidence, goes back to a time of strong Etruscan influence in Rome and would support the legendary account of its having been begun by Priscus and completed by Superbus. (R. B. Ld.)

**TARQUINIA** (ancient TARQUINII; medieval CORNETO) a town in the province of Viterbo, Italy, about 4 mi. (7 km.) inland from the Tyrrhenian Sea and 11 mi. (18 km.) N of Civitavecchia. Pop. (1961) 11,691. Its Latin name Tarquinii came from the Etruscan Tarchunia or Tarchna. It was a member of the Etruscan 12-city league, in which it enjoyed a certain primacy, especially in religious affairs. According to popular tradition, the city was founded by Tarchon, son of the Etruscan eponymous hero Tyrrhenus. But this story, and the local legend of a divine priest Tages who taught the Etruscans religious rites, are later inventions aimed at justifying the city's position of leadership under the powerful Tarquin (*q.v.*) family.

The earliest archaeological remains at Tarquinia are 9th-century B.C. Villanovan wall tombs (*tombe a pozzo*). The Etruscan tombs are mostly rock-cut chamber tombs dating from the 6th to the 4th century B.C., although in one such tomb was found a blue faience vase bearing the name of Bakenrenef (Bocchoris), an Egyptian pharaoh of the late 8th century. The main part of the necropolis is situated on the Monterozzi Hill, which comprises a ridge 3 mi. (5 km.) long to the SW of the ancient city, which occupies a position about 2 mi. (3 km.) NE of modern Tarquinia.

This necropolis contains the most important painted tombs in Etruria. The most famous of these is the "Fowling and Fishing Tomb," with its polychrome frescoes painted about 520 B.C. The "Tomb of the Lionesses" and "Tomb of the Leopards" show dancing and banquet scenes, as do the famous "Tomb of the Augurs" and the "Tomb of the Bacchants" (end of the 6th century B.C.). The "Tomb of the Triclinium" is the most outstanding 5th-century painted tomb, and the "Tomb of the Shields" is a masterpiece of 4th-century painting, while the polychrome frescoes of the "Tomb of Orcus and Polyphemus" also date from this century. A distinctive 2nd-century painting tradition, rare in Etruria, is found in the paintings of the "Tomb of the Cardinal."

The ancient city site was found on the hill La Civita by excavations carried out in 1934-38. Like other Etruscan cities, it was isolated and elevated. Remains of an imposing circle of walls have been uncovered, as well as the foundations of a great Etruscan temple known as the *Ara della Regina*, the decoration of which included a terra-cotta group of winged horses in Hellenistic style considered a masterpiece of Etruscan art. (See also ETRUSCANS.)

Tradition places the first wars between Tarquinii and Rome in 394 and 388 B.C. These were followed by a long campaign between 358 and 351. Forty years of peace followed, terminated by a short war in 311 in which Tarquinii was overcome by Rome and became a *civitas foederata*, retaining its oligarchic institutions. The 4th and 3rd centuries were a period of great prosperity and Greek, later Roman, influence in art and culture. In 181 the first Roman colony was founded on its territory. In 90 B.C. Tarquinii received Roman citizenship and a government of *quattuorviri jure dicundo*.

Tarquinii was the seat of a bishopric in the 5th century A.D., but by this time malaria had depopulated the coastal areas of the province. It was probably shortly after the Lombard invasion in the 6th century that the old city site ceased to be inhabited and the population transferred to the lower-lying city known in medieval times as Corneto, from 1922 as Tarquinia. Tarquinia contains many Romanesque buildings, chief of which is the church of Sta. Maria in Castello begun in 1121. Medieval fortifications and towers are still extant, and there is a fine Gothic palace, Palazzo Vitelleschi (1439), now the archaeological museum. (Wm. C.)

**TARRAGONA**, a town in the region of Catalonia in north-eastern Spain, and capital of Tarragona Province, is situated at the mouth of the Francolí River and on a hill (500 ft. [152 m.]) rising abruptly from the Mediterranean. Pop. (1960) 43,519. Located 60 mi. (96 km.) WSW of Barcelona, it is a flourishing seaport

and serves as an important agricultural market; it is also the seat of an archbishop and has a provincial court of justice.

Tarragona (Tarraco) is basically a Roman city. Once capital of an Iberian tribe, it was captured in 218 B.C. by Gnaeus and Publius Scipio, who improved its harbours and enlarged its walls, transforming it into the earliest Roman stronghold in Spain. Julius Caesar initiated its period of splendour and called it Colonia Julia Victrix Triumphalis to commemorate his victories. A temple was built in honour of Augustus, who made Tarraco the capital of Hispania Tarraconensis, and the so-called Castle of Pilate is supposed to have been his imperial palace. Hadrian and Trajan endowed Tarraco with power and cultural prestige, while its flux trade and other industries made it one of the richest seaports of the empire. Its fertile plain and beautiful sunny shores were praised by Martial, and its famous wines extolled by Pliny. According to tradition, St. Paul, with the help of St. Thecla, founded the Christian Church in Spain at Tarraco in A.D. 60. The city was razed by the Moors in 714 and remained unimportant until the beginning of the 12th century, when it was recaptured by the Christians, and the archbishopric, founded early in the Christian era, was restored. After 1119 Tarragona resumed its new life as an important city of the Spanish kingdom of Aragon, and from 11 James I organized the conquest of Majorca (1229). Having inherited from Rome an imperial sense of unity, Tarragona has shown a stubborn loyalty to the kings of Spain and has always been a bulwark against invaders. In the War of Independence it desperately resisted the French Army of General Louis Gabriel Suchet, and, when taken (1811), it was ruthlessly sacked and its people massacred.

Tarragona lies on the coastal road and on the Barcelona-Valencia and Barcelona-Madrid railway lines. The old quarter, with many houses built partly of Roman masonry, is more than half surrounded by the Roman wall and square towers from the time of the empire. In this sense Tarragona is unique, and seen from the hills in the north at sunset it offers a superb view. Roman ruins include the theatre, amphitheatre, circus, forum, and necropolis, and nearby, an aqueduct, the so-called Tomb of the Scipios, and the Triumphal Arch of Bara. The cathedral (12th-13th century) is transitional between Romanesque and Gothic, with a very fine cloister. Many interesting buildings and patios of the Medieval and Baroque periods line the streets.

The most important avenues are the Rambla de San Carlos and the Rambla de San Juan, the streets of Apodaca and Union, and the beautiful palm-tree walk linking the two *ramblas*. Along with some fine parks and sports grounds, Tarragona has a Pontifical University, a school of arts and crafts, a large technical school specializing in industrial studies, a few important day and boarding schools, convents, libraries, museums, and a bullring.

**TARRAGONA PROVINCE** (area 2,426 sq.mi. [6,283 sq.km.]; pop. [1960] 362,679) contains mountains to the northwest and beautifully cultivated plains by the sea. It is known for its wines, hazelnuts, almonds, olive trees, wheat, tomatoes, fruit, and vegetables. Important towns in the province include Vendrell, Valls, Reus, and Tortosa. Important medieval monasteries are those of Poblet and Santas Creus, 25 and 15 mi. (40 and 24 km.) from Tarragona, respectively. Torredembarra, Cambrils, and San Carlos are pleasant fishing villages along the coast, and Selou (Vilaseca) is an excellent summer and winter resort. (E. Pr.)

**TARRASA**, a town in the province of Barcelona, Spain, 19 mi. (31 km.) NW of Barcelona city. Pop. (1960; mun.) 92,234. The successor of the Roman Egara, it became in 450 an important episcopal see with a cathedral, later destroyed. Existing historic churches include the 12th-century Romanesque Santa Maria and San Pedro, both of which have a 6th-century apse; the former church contains 9th-century primitive paintings. The baptistery of San Miguel probably dates from the 6th century. In the Santo Espiritu Church, begun in 1575, is an alabaster figure of Christ sculpted in 1544. The 12th-century castle (later a Carthusian monastery) has undergone reconstruction and houses the town museum. There is a museum of historic textiles, and a school for textile engineers which is unique in Spain. The town's main manufacture has for centuries been woollens; other products are nylon

cottons, carpets, mosaics, and glass. There are also mechanical and electrical concerns. Tarrasa has rail and road connections with Barcelona and Saragossa. (M. P. Tr.)

**TARS, LOW-TEMPERATURE**, the primary condensation products resulting from the carbonization of coal and such other organic substances as wood, peat and lignite at temperatures not exceeding 700° C. The term low-temperature tar usually refers to a low-temperature coal tar.

**Wood Tar.**—This tar is a by-product of the carbonization of wood. Two distinct types of wood tar are recognized: (1) hardwood tar and (2) resinous wood tar, the former derived from woods such as oak and beech, and the latter from resinous stumps and roots, particularly from pine wood.

**Hardwood Tars.**—The condensed volatile product of wood distillation is known as crude pyroligneous acid, which has the average composition: water 81%, methyl alcohol 3%–4%, acetic acid 6%–8%, tar 7%. After settling, the major portion of the tar separates from the aqueous acid although the latter always retains some tar in solution. The chemical constituents of wood tar form a complex mixture comprising the fatty acids, esters, ketones, alcohols, phenols (usually polyhydric) and their methyl ethers, together with waxes. The most important representatives of these groups present in the tar are formic and acetic acids, with their methyl esters, acetone, methyl and allyl alcohol, guaiacol, catechol, and esters of pyrogallol.

Beechwood tar is practically the only wood tar subjected to a complete straight distillation. Three fractions are usually collected, first the light oils and water containing acetic acid and methyl alcohol up to 180° C., then the heavy oils up to 240° C. and finally the pitch. The important fraction is the heavy oil from which beechwood creosote is obtained (see CREOSOTE).

The oils from wood tar are used as gum inhibitors in gasoline and as flotation oils; the pitch is used in briquetting (see FUELS).

**Resinous Wood Tars.**—These tars are represented by pine-wood tar, which is commonly termed Stockholm or Archangel tar and is made extensively in the forests of the U.S.S.R., Finland and Sweden. It is an important commercial product and differs from hardwood tar in containing the pleasant smelling mixture of terpenes known as turpentine. Pine-wood tar is the residue left after the turpentine has been distilled, usually with the aid of steam. It is used widely in the manufacture of cordage, e.g., tarred ropes and twine, and for impregnation of hemp fibre for oakum. It is used to a slight extent in pharmacy as a component of some ointments and antiseptics. Distillates of pine-wood tar, particularly the creosote fraction, are used in froth flotation processes (see METALLURGY).

**Peat Tar.**—A jet-black, semisolid oil, lighter than water, this can be dehydrated by heating at 100° C. On distillation up to 360° C. a hard pitch is obtained along with an oily distillate, the latter consisting of a neutral fraction, containing the solid waxes, phenols and only traces of basic compounds. The most striking characteristic of the neutral oils is their high degree of unsaturation as manifested by absorption of atmospheric oxygen. The waxes, which resemble the montan wax of lignite, melt at about 40° C. The acidic (phenolic) constituents of the tar consist of phenol and its homologues, the cresols and xylenols in small quantity, mixed with tar acids boiling at 250°–360° C. The latter show a carbolic acid coefficient of 31, i.e., they are 31 times more powerful than phenol as bactericides. Among the phenolic constituents of peat tar, guaiacol, methylguaiacol and a methyl ether of pyrogallol have been identified. These ethers are absent from coal tar, but are found in wood-tar creosote, of which they form the major portion.

Peat tar may therefore be looked on as one of the transition steps from wood tar to coal tar. Although the products which can be isolated from peat tar are of undoubted value, the difficulty of winning and drying peat militates against the carbonization of this fuel on an industrial scale (see PEAT).

**Lignite and Brown Coal Tars.**—These tars resemble peat tar. They are usually black oils of rather buttery consistency owing to the presence of paraffin wax. Of an average density of 0.95, they retain a high percentage of water but solidify com-

pletely at 6°–8° C. In contradistinction to tars from bituminous coal, they are almost completely soluble in gasoline, a residue of only about 5% being usually left.

They are paraffinoid in nature, the wax content being as high as 10%. The crude wax melts at about 40° C. but from it a series of waxes with melting points from 46° to 73° C. has been obtained. The phenolic constituents resemble those of peat tar and are efficient bactericides. The basic components belong to the pyridine and quinoline series and are chiefly methylated derivatives. A distinctive characteristic of lignite tars is the presence of ketones in the neutral oils—a resemblance to the oils of wood tar. Lignite tars are of increasing importance as a source of fuels for internal-combustion engines, burning and lubricating oils and pitch (see LIGNITE).

**Low-Temperature Coal Tars.**—Vacuum tar has only been produced experimentally with the object of elucidating the composition of coal and the effect of heat upon this material. It is obtained when coal is carbonized at temperatures up to 450° C. under a pressure of 5–40 mm. Hg; the average yield is 14 gal. (6.5% by weight) per ton of coal. It is usually lighter than water (0.99 sp.gr.) and is especially interesting in that some of its constituents are identical with substances found in petroleum oils, and extractable from coal itself by solvents such as pyridine. It consists of 40%–45% paraffins and naphthenes, 40% ethylenic hydrocarbons richer in carbon than monoolefins, 7% aromatic hydrocarbons, chiefly homologues of naphthalene, and 10% phenols, mostly cresols and xylenols, with smaller amounts of tertiary alcohols and basic compounds. Naphthalene, anthracene, benzene and its homologues are all absent.

Among the more interesting constituents of vacuum tar are the naphthene,  $C_{30}H_{60}$ , called melene, which is also found in Galician petroleum and in the distillate of beeswax, and the hydrogenated phenols (alcohols) such as hexahydro-*p*-cresol and its homologues.

Low-temperature tar is produced by the carbonization of bituminous coals, containing 28%–35% volatile matter, at temperatures not exceeding 700° C., which is an optimum temperature for the production of gas, tar and smokeless fuel (see CARBONIZATION, LOW-TEMPERATURE). It is essentially a mixture of those volatile products of coal which are liquid at ordinary temperatures and which have not been subjected to the secondary thermal decomposition incidental to high-temperature carbonization in horizontal retorts. It is therefore regarded as a primary tar and has a widely varying composition.

Low-temperature tar is usually a brownish black oil, much less viscous than the tar made from the same coal at high temperatures. It is obtained in an average yield of 16–18 gal. per ton of coal carbonized, or 8%–9% by weight. This is approximately double the weight obtained by distilling the coal at 900°–1,200° C. Its specific gravity is 1.02–1.07, and owing to the low temperature at which it is formed, it is mainly paraffinoid in character, whereas high-temperature tar is almost wholly aromatic. The most distinctive characteristics of low-temperature tar are the almost entire absence of benzene and its homologues, naphthalene, anthracene and phenol; the unsaturated nature of the neutral oils, from which can be isolated solid paraffins; and the presence of solid, amorphous compounds, of either basic or phenolic nature.

The crude tar is a most unstable product and begins to decompose at about 200° C., finally yielding, when distilled to 360° C., an average of 65% oily distillate and 35% pitch. The amount of pitch formed on distilling low-temperature tar is therefore only half that obtained in a similar operation with high-temperature tar. The former, too, contains much less free carbon (i.e., matter insoluble in benzene) than the latter, the average amount being 2%–4%. By modified extractions with caustic soda and sulfuric acid (see COAL TAR) the crude distillate can be divided into (1) neutral oils; (2) phenols; and (3) bases.

**Neutral Oils.**—These consist mostly of paraffins, naphthenes and olefins, with comparatively small amounts of methylated derivatives of naphthalene and anthracene. On treatment with concentrated sulfuric acid, the neutral oils are absorbed with the exception of some 12% consisting mainly of paraffins. Crude

solid wax representing over 1% of the tar is obtained on cooling an acetone solution of the neutral oils. In the paraffin series, all the lower members have been identified, and in the higher ranges, the solid members from  $C_{26}H_{54}$  to  $C_{29}H_{60}$ . The latter melt at  $62^\circ$  C.  $\alpha$ - and  $\beta$ -methylanthracenes have been isolated, but no naphthalene. Similarly  $\beta$ -methylanthracene occurs in a complex mixture of hydrocarbons crystallizing on cooling the high fractions of the distillates, but anthracene is absent. Neither fluorene nor carbazole has been identified in low-temperature tar; in addition to the hydrocarbons acenaphthene and diphenyl, there occur the fully hydrogenated products, perhydrofluorene, perhydroacenaphthene and dodecahydrodiphenyl.

**Phenols.**—The extraction of the phenolic constituents of the tar or its distillates is complicated by the fact that resinous and asphaltic substances accompany the phenols in solution in the alkali. These impurities, however, can be eliminated by agitation of the alkaline solution with organic solvents or by saturation with salt. The crude phenols (10%–20% of the tar) obtained on acidification as a black oil, can be further purified by extraction with light petroleum, followed by precipitation of the residue from an ethereal solution by fresh petroleum. The petroleum extract consists of low-boiling phenols including phenol itself, the cresols and 1,2,4-, 1,3,5-, 1,3,4-, and 1,4,2- xylenols. Catechol,  $\beta$ -naphthol and trimethylphenols have also been identified. The higher phenols of the tar are amorphous solids varying in colour from pale yellow to black.

**Bases.**—The crude bases, representing 2%–3% of the tar, are also composed of a low mobile fraction and a higher viscous fraction containing solid, amorphous substances of unknown constitution. The lower bases consist of pyridine and quinoline with their mono-, di- and tri- methyl derivatives. Only traces of primary bases are present in the tar. There have been identified pyridine, 2-methylpyridine, 3-methylpyridine, 4-methylpyridine, 2,5-dimethylpyridine, 3,4-dimethylpyridine, 2,4,5-trimethylpyridine, 2,3,4-trimethylpyridine, 2,4,6-trimethylpyridine, aniline, 2,3,5-trimethylpyridine, *p*-, *o*- and *m*-toluidine, 2,3,4,5-tetramethylpyridine, quinoline, isoquinoline, and 2-methylquinoline.

**Utilization of Low-Temperature Tar Products.**—The commercial possibilities of low-temperature tar have not yet been fully developed, but its application in various directions has been demonstrated. The low-boiling distillates, owing to their unsaturated nature (see HYDROCARBON), form satisfactory fuel possessing certain antidetonating qualities. It has been claimed that the higher fractions of the neutral oils form an exceptionally good lubricant, while the so-called middle or dead oils are suitable for combustion in the diesel engine. Special characteristics are also claimed for low-temperature tar pitch, which can be used along with or in place of high-temperature tar pitch.

See H. H. Lowry, *Chemistry of Coal Utilization*, (1945), supplementary vol. (1963). (D. D. P.; F. E. Cr.)

**TARSIER**, a small primate of interest as an intermediate form between the lemur and the monkey. Tarsiers are represented today by one genus, *Tarsius*, and several species, constituting the suborder Tarsioidae (or Tarsiiformes). They inhabit several islands of southeast Asia, including the southern Philippines, Celebes, Borneo, and Sumatra. (For the tarsier mixture of advanced and primitive features and the evidence of its fossil remains, see PRIMATES.)

The spectral tarsier (*T. spectrum*), to which species all forms are sometimes referred by some authors, is rarely more than 16 cm. (about 6 in.) in body length, and the tail up to twice that length. Its silky fur ranges from buff to dark brown. The tarsier is well adapted to an arboreal life by the great elongation of its hind limbs (the ankle region, or tarsus, being especially affected—the feature to which the animal owes its name); the expansion of the tips of its digits into disklike adhesive pads; and the long, thin tail, tufted at the end, which serves as a balancer during flight and as a stabilizer and prop during climbing. Its rounded head, which can be rotated through  $180^\circ$ , has a shortened face with large goggling eyes, the most striking feature; the eyes face farther forward than those of lemurs. Its ears are large and membranous and almost constantly in motion, being furled or crinkled.

These are nocturnal and twilight-active animals. They prey mainly on insects for food but also take a little fruit. Except during the breeding season, tarsiers live alone. A single young is produced in a fairly well-developed state, well furred and with eyes open.

(W. C. O. El.)

**TARSUS**, in southern Turkey, the birthplace of St. Paul (Acts 22:3), is a very ancient city on the Cydnus River (Tarsus Çay) in the alluvial plain of Cilicia in the Icel  $\#$ . Pop. (1965) 57,035. Excavations carried out under the guidance of Hetty Goldman before and immediately after World War II at Gözli Kule on the southwestern periphery of the modern town show that, with some interruptions, settlements existed there from the Neolithic to the Islamic period.

Tarsus' prosperity over more than a millennium, between the 5th century B.C. and the Arab invasions in the 7th century A.D., was primarily due to the fertility of its soil and its commanding position at the southern end of the road from Anatolia to Syria by way of the Cilician Gates, the only major pass in the Taurus Range. Through the gates Xenophon and, later, Alexander III the Great (q.v.) both passed with their armies. A third factor was the excellent and sheltered harbour of Rhégma, whereby Tarsus established strong maritime connections with the Levant and consequently absorbed many Semitic characteristics.

With less justification than many another Cilician city, Tarsus claimed a Hellenic origin, with Perseus and Heracles numbered among its mythical founders. In fact, the first authenticated appearance of the city in history is the record on a clay tablet of the rebuilding of Tarsus and Anchiale by the Assyrian king Sennacherib (705–681 B.C.) after an unsuccessful rebellion in Kue (Cilicia). After the decline of Assyrian power, Tarsus was ruled by native princes with the probably hereditary name or style of Syennesis. This local autonomy even continued under the Persian Empire, but in the 4th century the city was regularly administered by a satrap, and a series of coins was issued with legends in Aramaic. During the Macedonian occupation, the territory of Cilicia was disputed between the Seleucids and Ptolemies, and for a short time Tarsus was named Antioch-on-the Cydnus, apparently in honour of Antiochus Epiphanes. Thereafter it enjoyed an autonomy not far removed from anarchy until, with the crushing of the Cilician pirates by Pompey in 67 B.C., it was absorbed into the new Roman province of Cilicia. The city found favour with both Caesar and Mark Antony, and the royal progress of Cleopatra's sumptuous barge up the Cydnus to Tarsus, where the queen had an assignation with Antony, is one of the most memorable though not one of the most important events in the city's history. More important was the establishment of the university, where a flourishing school of Greek philosophy turned out such outstanding men as Athenodorus Cananites (q.v.), the teacher of Augustus.

During the Roman and early Byzantine periods, Tarsus was one of the leading cities of the Eastern Empire, its prosperity assured by its agriculture and an important linen industry. It styled itself "first, greatest, and most beautiful," "metropolis of the three provinces of Cilicia, Isauria, and Lycaonia." Its rivalry with Anazarbus (q.v.) was resolved when the province was divided in early Byzantine times into Cilicia Prima, with Tarsus as metropolis, and Cilicia Secunda, under the primacy of Anazarbus.

With the Arab onslaught on Cilicia soon after A.D. 660, Tarsus was laid in ruins, though a tenuous continuity of its greatness may be seen in the consecration of Theodore, an *émigré* Tarsiot, as archbishop of Canterbury in 668. More than a century later, in A.D. 787, the Abbasid caliph Harun al-Rashid rebuilt the city and transformed it into a military base for the Arab raiders who year after year invaded Byzantine territory by way of the Cilician Gates. The city's northern gate was consequently known as the Gate of the Holy War. The only surviving gate, the western, is still sometimes wrongly described as the Gate of St. Paul. In 965 all Cilicia was won back from the Muslims by the Byzantine emperor Nicephorus II Phocas, Tarsus surrendering after a siege. In 1097 the city was taken by the crusaders, but much more important was its absorption in the 12th century into the Christian kingdom of Little Armenia, of which it remained part until it was captured by the Mamelukes in 1359. A century and a half

later it had passed into the hands of the Ottomans.

Apart from the objects, now housed at Adana (about 25 mi. [40 km.] E of Tarsus), that were discovered at Gözlü Kule, little is known of the ruins of ancient Tarsus. A large concrete mass, known as the Frozen Stone (*Donuk Taş*), still to be seen above the surface, is almost certainly the substructure of a Roman public building. Chance finds of sculpture, mosaic, and sarcophagi are also made by workmen digging the foundations of new buildings.

Modern Tarsus is a wealthy commercial centre. Its climate much improved after the draining of the swamps that formerly made the city a hotbed of malaria. In the 6th century Justinian diverted the course of the Cydnus to drain off surplus water in time of flood; but as the old channel was later neglected for centuries, the river and its harbour were gradually silted up and became stagnant marshes. These were drained in the early days of the Turkish republic by the planting of a eucalyptus forest, and the river now flows through the eastern extremity of Tarsus.

**TARTAGLIA (TARTALEA), NICCOLÒ FONTANA** (1499–1559), Italian mathematician, originated the science of ballistics and contributed a method for solving cubic equations. He was born at Brescia, where he was brought up in poverty by his mother. During the sack of Brescia by the French Army (1512) the boy received sabre cuts on the head; the ensuing speech difficulties caused the nickname Tartaglia, the stutterer, which he adopted. In 1534 he settled in Venice as a teacher of mathematics. In 1535 he was challenged to a problem-solving contest by Antonio Maria Fiore, a pupil of Scipione del Ferro, professor of mathematics at Bologna. Del Ferro had discovered the solution to the cubic equation, but kept it secret; upon his death it passed to Fiore. All problems proposed by Fiore led to cubic equations and when Tartaglia rediscovered the solution his victory was assured.

In 1537 appeared Tartaglia's first work, *Nova Scientia*, a treatise on gunnery, important as a pioneer attempt to establish the laws of falling bodies. Shortly afterward Tartaglia was approached by Girolamo Cardano (*q.v.*), physician and lecturer in Milan, requesting that Tartaglia publish his solution of the cubic or let Cardano include it in his forthcoming book. This Tartaglia refused, but on a later visit to Milan, hoping to become adviser on artillery to the Spanish Army, he confided the solution to Cardano under promise of secrecy. In 1545 appeared Cardano's *Ars Magna*, giving the solution to the cubic as well as the quartic, the latter discovered by his pupil, Lodovico Ferrari. Tartaglia responded in *Questioni et inventioni diverse* (1546), a collection of problems proposed to him by prominent men and dedicated to Henry VIII. He berated Cardano for his breach of faith; this led to a sequence of six printed cartels and counter-cartels between Ferrari and Tartaglia. The feud culminated in a public dispute in Milan, Aug. 10 1548, which Ferrari apparently won. Tartaglia lost his position as public lecturer at Brescia and returned to Venice. His troubles in Brescia are described in the *Travagliata inventione* (1551). Best known is his *Trattato di numeri et misure*, three volumes (1556–60), an encyclopaedic work on elementary mathematics. Tartaglia also published translations of Euclid and Archimedes. He died in Venice, Dec. 13, 1559. His works were published as *Opere del famosissimo Nicola Tartaglia* (1606). (O. Oe.)

**TARTAN** is a cross-checked repeating pattern, or "sett," of differently coloured bands, stripes, or lines of definite width and sequence, woven into woolen cloth (sometimes with silk added). Such patterns have existed for centuries in various countries and may be found in a Japanese print or in a primitive Sienese painting but nowadays have come to be regarded as peculiarly Scottish and, throughout the English-speaking world, as being a quasi-heraldic Scottish family device. Tartans were often used for the old Highland "belted plaid," a rectangular piece of cloth confined by a belt round the wearer's waist, below which it fell in rough pleats (sometimes sewn). The upper, larger portion was brought up to form a kind of cloak around the shoulders. From this garment the

smaller kilt appears to have originated in the earlier part of the 17th century.

**History.**—Great significance and antiquity have long been claimed for many Scottish family or clan tartans; but the meagre references to "tartan" that can be gleaned from 15th- and 16th-century writings are somewhat overworked. Confusion and rash assumptions may well have arisen from the variety of spellings encountered therein and from the meanings of old words.

Proof of the antiquity of a tartan as a family or clan badge can only be satisfactory in the form of a specimen of the material, accompanied by contemporary evidence as to its significance; for example, the documentation afforded by at least two portraits of members of the same family or clan wearing the same tartan. From the earliest known painted representation of the Highland dress, J. Michael Wright's "Highland Chieftain," in the Scottish National Portrait Gallery, Edinburgh, all that can be learned is that a small cross-check or "tartan" pattern was adapted to use in kilt, plaid, and hose about 1660. The chieftain is believed to be a Campbell, but no stretch of imagination will relate the pattern that he wears to that of any "Campbell" tartan (or any other established tartan) of today. The 18th century, however, provides a substantial number of portraits forming a reliable pictorial record of some tartans. But the pleasantly naïve painter Richard Waitt, practising in the first quarter of the century, seems to prove by his collection of portraits of members of the Grant clan, all in plaids of different tartan, that these can have no clan or family significance. The Swiss David Morier, military painter to King George II, provides evidence, in his exciting "An Incident in the Rebellion of 1745" (at Windsor Castle), that an individual clansman in Prince Charles's army might wear coat, waistcoat, plaid or kilt, and hose, each of different tartan. Some of the patterns resemble those of today: B. du Pan's "Children of the Prince of Wales" (1746, also at Windsor) shows the eldest, Prince George (later George III), in dress of the Royal Company of Archers of a design remarkably close to that of the modern Royal Stewart tartan. It seems very odd that a Hanoverian prince should be wearing a pattern of such significance at the date of this picture (1746). But there is little doubt that portraits dating from the latter half of the 18th century show the Highland gentleman wearing such tartan as pleased him in colour and design, including different garments of unrelated tartans. (It must of course be recognized that in particular localities of the somewhat primitive Highlands, weavers would be tenacious of preferences and traditions in design; and that local dyes might be prevalent.)

Highland dress and the tartan were proscribed after the Jacobite rising of 1745 (*i.e.*, from 1746 to 1782). However, the Highland regiments of the latter 18th century wore tartan; therefore, uniform military tartans came to be designed. A number of these, mostly based on the earliest, that of the 42nd Regiment of Foot or "Black Watch" (which was frequently termed "government" tartan), have survived as approved "clan" tartans. The result of permitting military tartans may well have been to modify the effects of the proscription. There is little doubt that much of the present interest in, and affection for, the tartan can be attributed to its official military employment and to the honours won by the Highland regiments. This led during the first half of the 20th century, however, to the introduction (deplored by many) of "fancy" tartans with no military traditions to support their adoption.

The largely military revival of tartan from the late decades of the 18th century seems to have reached a high peak during the state visit of George IV to Edinburgh in 1822. The following three decades saw undiminished interest and produced an imaginative and systematic recording of "clan tartans" (rather lacking in integrity, perhaps) by authors and artists, creating what has been called "The Great Tartan Myth." Intermittent efforts to explode this in the interest of historic truth have failed: 150 years of the combined efforts of artists, writers, publishers, manufacturers, and tailors had created a tradition and firmly established tartan as a Scottish clan badge. (A. E. H. M.)

**Current Practice.**—Most clans have but one tartan, though, where this is bright, a muted pattern called a hunting sett is used for everyday wear on the moors and mountains. The "dress

tartan," a modern conception, has sometimes been represented in the market by white-based tartans, which do not look well on men and were not meant for them. White-based tartans were known originally as "arisaid setts" and were worn by women, on whom they do look well. The gray-based setts (quite a different matter) are often the groundwork of a true hunting tartan. Women's tartan dress (with varying local corsages) continued to be worn in the glens and has latterly enjoyed some revival. The uniforms of certain Scottish regiments provided for trousers, or "trews," of tartan and for riding breeches of tartan.

The antecedents of modern tartan dress, as has been said above, emerge from the mists of antiquity—though portraits of chieftains, their pipers, and other officers of their households in more recent times are an important source of evidence of dress detail and, latterly, of clan tartan. This evidence is sounder than that of the tartan books that began to be issued in the 19th century. Another, though limited, source is the Public Register of All Arms and Bearings in Scotland where, in the few cases in which verbal armorial blazon on parchment is accompanied by a miniature emblazonment, the latter can be made up into a kilt-size sett. Discretion is necessary in working such emblazonments out into setts, but they can be taken to show the general hue and special characters of quite a number of tartans. Such sources are considered by Lyon Court (presided over by Lord Lyon King of Arms) through which tartans are authorized and registered; and the chiefs of clans are consulted too. About 1950 a tartan committee was set up by Lord Lyon. The committee considers matters remitted to it by Lyon Court, from the standpoint of reporting on historical and practical aspects of setts which Lyon Court is being asked to use in this or that application. Its observations are considered and sanctioned by Lord Lyon King of Arms (where necessary in consultation also with the Standing Council of Scottish Chiefs) and become a guide and instruction for tartan weavers and outfitters. The result is that a number of tartans have been given statutory certainty from their inclusion in duly registered armorial bearings. This has regularized the commercial manufacture and sale of tartans, so that registered tartans are correctly reproduced—even though commercial pseudo-tartans and checks have continued to increase, and though an individual cannot be prevented from inventing a sett and having it made up to order.

The Scottish Tartan Centre, founded at Stirling in the mid-1960s, makes an intensive study of tartans. Its collections (including those of the early 19th-century weavers Wilson's of Bannockburn) supplement the earlier collections of Moy Hall (the Inverness-shire seat of the Mackintosh) and of the Highland Society of London, and are of growing use in clarifying the history and details of tartans and Highland dress and in providing valuable evidence when required for consideration in Lyon Court.

To the frequent modern question: "What is my tartan?" the answer is: "The one applicable to your surname"—if it be the name of any clan, sept, or great family. Name-spelling is usually immaterial, because it was chaotic until the mid-19th century. If of no clan or sept a person of Scottish connection may find there is a "district tartan" applicable to his ancestors' "habitat." Several "Scottish" general tartans are also available. (T. I.)

Haswell Miller, "The Truth About the Tartan," *Scotland's Magazine* (Edinburgh, Nov. 1947). The Scottish National Portrait Gallery, Edinburgh, contains a unique collection of photographs, manuscript notes, and drawings of contemporary portraits recording Highland dress. (A. E. H. M.)

**TARTAR:** see TARTARIC ACID.

**TARTARIC ACID** is one of the most important of the organic acids. Its sparingly soluble acid salt was known to the

Greeks and Romans as a deposit in wine casks or vats during the fermentation of grape juice to wine. This crude crystalline crust of argol, which contains about 75% potassium acid tartrate (bitartrate), can be partly purified by recrystallization to tartar. When further purified, it becomes cream of tartar. K. W. Scheele first isolated tartaric acid in 1769 by boiling tartar with chalk and decomposing the product with sulfuric acid. Tartaric acid crystallizes from water in colourless monoclinic prisms. At ordinary temperatures these crystals are free of water of crystallization have the composition  $C_4H_6O_6$  and melt at  $169^{\circ}$ – $170^{\circ}$  C. Tartaric acid, assigned the structural formula  $HO_2CCHOHCHOHCO_2H$ , belongs to the hydroxy polycarboxylic acids.

**Manufacture.**—The by-products of wine fermentation, press cakes from grape juice, lees (dried slimy sediments) and argols constitute the raw materials from which tartaric acid, cream of tartar and Rochelle salt (potassium sodium tartrate) are made. The raw materials containing impurities are subjected either to steam autoclaving at 50–60 lb. pressure or dry roasting at  $150^{\circ}$ – $160^{\circ}$  C. The crude tartar is indirectly heated in the dry state suspended in water, then neutralized with calcium hydroxide; the precipitated calcium tartrate is filtered. The filtrate is evaporated for recovery of potassium sulfate, and the cake is treated with sulfuric acid. Sparingly soluble calcium sulfate remains largely undissolved, whereas the tartaric acid passes into solution. The dilute liquor is concentrated to the crystallizing point in vacuum pans and cooled. The crude product is redissolved in water, treated with chemicals to remove impurities and decolorized by heating with charcoal. The filtered colourless solution is concentrated and allowed to crystallize. After the granular material is removed by centrifugation and dried in a rotary drier, the pure tartaric acid meets the requirements specified in the *United States Pharmacopeia*. Rochelle salt is prepared from argols blended to contain 75%–85% potassium bitartrate and less than 6% calcium tartrate. The roasted product is neutralized with sodium carbonate, clarified and evaporated to crystallize the Rochelle salt. Cream of tartar (potassium hydrogen tartrate) is usually produced by mixing filtrates from the manufacture of tartaric acid, Rochelle salt and potassium sulfate. After purification and decolorization with carbon, the material is allowed to precipitate under acid conditions. Tartar emetic (antimony potassium tartrate) is prepared by heating in water, 3.4 parts of antimony oxide and 4.3 parts of potassium bitartrate. The product separates in colourless transparent crystals which gradually lose water of crystallization, becoming opaque.

**Applications.**—Tartaric acid is widely used in carbonated drinks, effervescent tablets and powders and as an acidulant in gelatin, dessert and fruit jellies. It has many industrial applications; e.g., in the cleaning and polishing of metals, in calico printing for controlling the liberation of chlorine from bleaching powder as a mordant in wool dyeing, in certain photographic processes for printing and developing, and as ferric tartrate in blueprinting. Rochelle salt is used extensively in the silvering of mirrors, as a component of crystal-controlled electronic oscillators, in the processing of cheese and as a mild cathartic in drug preparations. Cream of tartar is employed in baking powders, in hard candies and taffies for its ability to invert cane sugar, as a cleaner of brass in the electrolytic tinning of iron and steel and in gold and silver coating of metals. Tartar emetic is used extensively in therapeutics for nauseant, expectorant and emetic effects. In tropical infections such as trypanosomiasis and kala azar, it is administered intravenously. Tartar emetic finds use in other varied fields; e.g., in the control of insects on farms and as a mordant in fixing basic colours on cotton, leather and fur.

**Chemical Reactions.**—Tartaric acid is oxidized by hydrogen peroxide in the presence of ferrous salts to dihydroxymaleic acid. Reduction with hydrogen iodide forms first *d*-malic and finally succinic acids. Heating forms pyruvic and pyrotartaric acids and finally a black residue. Ammoniacal silver solution is reduced with the formation of a silver mirror. Tartaric acid has the ability to form complex metal ions with aluminum, iron, copper and lead, and prevents their precipitation on the addition of bases.

**Stereoisomeric Tartaric Acids.**—Four varieties of tartaric acid are recognized: (1) the ordinary dextrorotatory tartaric acid

found either free or as potassium and calcium tartrates in the juices of tamarinds, mulberries, pineapples, unripe beetroot and especially in grapes; (2) levorotatory tartaric acid, which occurs naturally in the fruit and leaves of *Bauhinia reticulata*, a native tree of the Mali Republic, but which originally was obtained by the resolutions of the salts of racemic acid. Except as regards its interactions with other optically active substances, its chemical properties are identical with those of the dextro-acid and in all its physical properties it resembles this acid except that it turns the plane of polarization of light to the left and its crystalline salts show hemihedral faces like those of the dextro-acid, but oppositely situated, as object to mirror image; (3) racemic acid,  $(C_4H_6O_6)_2 \cdot 2H_2O$ , which is obtained from the tartar mother liquor and dried at  $110^\circ C$ . to the anhydrous form, melts at  $206^\circ C$ . It is produced synthetically by oxidation of fumaric acid, by hydroxylation of fumaric or maleic acids, or by mixing molecular proportions of the *d*- and *l*-acids; (4) mesotartaric acid is obtained when cinchonine tartrate or *d*-tartaric acid or its alkali salts are heated for prolonged periods at  $170^\circ C$ . The anhydrous form of the acid melts at  $159$ – $160^\circ C$ . The meso form can be synthesized by hydroxylation of fumaric or maleic acids. It is inactive like racemic acid but rather for the reason that the molecule has a plane of symmetry. Unlike the racemic mixture, it is not resolvable into optically active varieties. The chemical study of the optical properties of these four tartaric acids by Louis Pasteur forms the foundation of modern conceptions of stereoisomerism. See STEREOCHEMISTRY. (P. P. R.)

**TARTARS:** see TATAR.

**TARTINI, GIUSEPPE** (1692–1770), Italian violinist, composer, and theorist who helped establish the modern style of violin bowing and who formulated principles of ornamentation and harmony. Born at Pirano, Istria, on April 8, 1692, he studied divinity and law at Padua and at the same time established a reputation in fencing. Before the age of 20 he secretly married a protégée of the archbishop of Padua, resulting eventually in his arrest. Disguised as a monk, he fled from Padua and took refuge in a monastery at Assisi. There his violin playing attracted attention and ultimately influenced the archbishop in his decision to allow Tartini to return to his wife at Padua. In 1716 he went to Venice, where he rivaled the reputation of F. M. Veracini. Later he was at Ancona and eventually returned to Padua, where he was appointed principal violinist at the Church of S. Antonio in 1721. From 1723 to 1725 he directed the orchestra of the chancellor of Bohemia in Prague. In 1726 he returned to Padua, where, two years later, he founded a school of violin playing and composition. He made only one concert tour of Italy, in 1740. He died at Padua on Feb. 26, 1770.

Tartini's playing was said to be remarkable for its combination of technical and poetic qualities, and his bowing became a model for later schools of violinists. P. Nardini, G. Pugnani, and A. N. Paganini were among his pupils. His works include about 200 violin concertos and the same number of violin sonatas, though only a small number of them were published. The sonata entitled "Trillo del Diavolo" (Devil's Trill), written after 1735, was discovered by P. M. F. Baillol and was first published in J. B. Cartier's *L'Art du Violon* (1798). Tartini also wrote quartets, trios, symphonies, and, toward the end of his life, religious works, including a five-part *Miserere* and a four-part *Salve Regina*.

He contributed to the science of acoustics by his discovery that when any two notes are produced steadily and with intensity, a third note, known as the "difference tone," is heard. This discovery was of help in allowing violinists to play in time more reliably. Accordingly Tartini held that double stopping on the violin was not in tune unless the player could hear this difference tone. He also devised a theory of harmony based on affinities with algebra and geometry. He made these observations the basis of a theoretical system that he set forth in his *Trattato di musica* (1754), expanded into *Dissertazione dei principi dell'armonia musicale* (1767). An English translation of this work, an "Account of Tartini's Treatise on Music" by B. Stillingsfleet, is contained in *Principles and Power of Harmony* (1771). Tartini's theoretical works also include *Trattato delle appoggiature*, a treatise

on ornamentation. *Delle ragioni e delle proporzioni*, long attributed to Tartini, is by the mathematician Don A. Colombo and contains a list of Tartini's theoretical writings. A letter on violin playing, addressed to his pupil M. Lombardini, was translated into English by Charles Burney (1771).

See M. Dounias, *Die Violinkonzerte G. Tartinis* (1935); A. Capri, *G. Tartini* (1945). (Cs. Cu.)

**TARTU** (German DORPAT), an old university town of the Estonian Soviet Socialist Republic, U.S.S.R., is on the Emajõgi River in the east-central part of the republic. Pop. (1959) 74,263. The principal section of the town lies south of the river, and the more important buildings are clustered around the ruins of a 13th-century cathedral.

The town's history dates back to 1030, when the Russian prince Yaroslav I erected a fort on a site called Yur'yev. From about 1224, when it was seized by the Teutonic Knights, until it was captured by the Russians about 1558, the town enjoyed great prosperity. Then for more than a century Tartu was held alternately by the Swedes, the Poles, and the Russians until, in 1704, it was annexed to the Russian Empire, and four years later the bulk of Tartu's population was deported to the interior of Russia. Following a devastating fire about 1777, the town was almost entirely rebuilt and its fortifications transformed into tree-lined promenades. The town passed to Estonian rule in 1918, but in 1940 it fell under Soviet occupation. Tartu was severely damaged during World War II under the Germans (1941–44) but later, as a part of the Soviet Union, became important for production of agricultural machinery, footwear, foodstuffs, and lumber.

The University of Tartu, chartered by Gustavus II Adolphus of Sweden in 1632, was evacuated to Parnu on the advance of the Russians in 1699. In 1710, when Parnu was also besieged, the university was closed until, in 1802, it was reopened at Tartu. German influence predominated in the university until the russification of the 1890s. Though in 1919 the institution reflected Estonia's independence as the Estonian University, Soviet influence has predominated. The university is noted for its observatory, art museum, botanical garden, and its library of more than 2,250,000 volumes. In 1951 another higher educational institution, the Academy of Agriculture, was established in Tartu.

**TARXIEN:** see MALTA: *Archaeology*; PAOLA-TARXIEN.

**TASHKENT**, an oblast of the Uzbek Soviet Socialist Republic, U.S.S.R., was founded in 1938. It adjoins the Kazakh, Kirgiz, and Tadzhik S.S.R.'s and has an area of 6,023 sq.mi. (15,600 sq.km.). It is divided into 13 *rayons* and has 9 towns and 14 "settlements of town type." The oblast is situated at the northwestern edge of the Tien Shan (Tyan' Shan') Mountains in the basin of the middle course of the Syr-Dar'ya. Most of its territory consists of a plain intersected by the Syr-Dar'ya, Angren, and Chirchik rivers. The northeast is mountainous (Kuraminskiy, Ugamskiy, and Pskemskiy ranges), with peaks rising to 14,000 ft. (4,250 m.); the Golodnaya Step' (Hungry Steppe) occupies the southwestern part. The climate is continental, with a mild winter and a long, hot, dry summer. Rainfall varies from 10 in. (250 mm.) in the plains to 20 in. (500 mm.) in the foothills and mountains.

In 1959 the population was 2,260,881 (58% urban), of whom about 40% were Uzbeks and 29% Russians, the majority of the latter living in Tashkent. The rest are Kazakhs, Tatars, Ukrainians, Tadzhiks, and Koreans (about 3%). The towns are Tashkent, Chirchik, Angren, Almalyk, Yangi-Yul', Begovat, Mirzachul', Yangi-Abad, Yangi-Yer.

Industrially, the oblast is highly developed and includes about 3,000 factories. The geographical position has promoted industry connected with metal processing, machine construction, and other enterprises working on imported raw materials. There are agricultural machinery works, railway workshops, cotton textile and paper mills, and clothing and shoe factories. Food industries include meat-packing, flour milling, and fruit and vegetable canning. Brown coal is mined at Angren. Large electric power stations at Farkhad, Chirchik, Nizhne-Bozsu, and Ordzhonikidze provide 90% of the power used. The main crop is cotton, which provides more than 20% of Uzbekistan's total output. Of the total sown area of 155,000 ha. (about 380,000 ac.), more than two-thirds is

devoted to cotton. Jute and oleiferous plants (such as flax and sesame) and vegetables and melons are grown. Livestock breeding includes pedigree cattle centres in the Chinaz and Mirzachul' rayons.

The main Moscow-Tashkent-Krasnovodsk railway traverses the *oblast*, with Ursat'yevskaya the junction for the Fergana Valley railway. From Tashkent branch lines run to Chirchik and Angren. Of the extensive network of roads, the principal are the Tashkent-Termez and Tashkent-Dushanbe routes.

There are in the *oblast* more than 20 professional schools and 40 "middle" special training establishments, including mining, industrial, electromechanical, and cotton-ginning *tekhnikums*. There were 18 higher educational establishments (including the Tashkent V. I. Lenin University). (G. E. Wr.)

**TASHKENT**, the capital of Tashkentskaya (Tashkent) Oblast', and also capital of the Uzbek Soviet Socialist Republic, U.S.S.R., from 1930. Pop. (1959) 911,930. Though it is one of the oldest and largest cities of Central Asia, about half the population is composed of Russians and other non-Asians.

Probably founded in the 6th or 7th century, Tashkent was taken by the Arabs early in the 8th century A.D. It was important economically until the beginning of the 13th century, when it was destroyed by the khan of East Turkistan, Kuchluk. Rebuilt in the middle of the 13th century, it became part of the Timurid Empire until the end of the 15th, when it resumed a partly independent economic existence. From the beginning of the 19th century it was part of the Kokand khanate and was captured by the Russians in 1865, when it became the commercial, cultural, and administrative centre of Russian Turkistan. The new city, built under the tsarist regime, was greatly developed after the Revolution, but much of the old city with its 12 gates still remains. It is the headquarters of the Turkistan Military District.

Tashkent has many major heavy-industry enterprises, including textile, agricultural, and building machinery, and electrical and mining equipment. The most important light industry is the Tashkent textile *kombinat*. Abrasives, china and pottery, paper, furniture, and food and chemical products are also produced. Apart from the Tashkent V. I. Lenin University, the Uzbek Academy of Sciences, and 16 higher educational establishments, Tashkent contains many technical training establishments. Theatres include the Alisher Navoy Opera and Ballet Theatre and a puppet theatre. There are also a concert hall, circus, cinemas, and a cinema studio, and 11 parks and 4 stadiums. Many newspapers are published in the Uzbek, Tadjik, and Russian languages, and there are radio and television broadcasting stations.

(G. E. Wr.)

**TASMAN, ABEL JANSZON** (c. 1603–c. 1659), the greatest of Dutch navigators and explorers, the discoverer of Tasmania, New Zealand, the Tonga and the Fiji Islands, was born at Lutjegast in Groningen, probably in 1603. He entered the service of the Dutch East India company in 1632 or 1633. His first exploring voyage was to Ceram as captain of the "Mocha" in 1634. He sailed in 1639 under Matthew Quast on an expedition in search of the "islands of gold and silver" in the seas east of Japan. After a series of trading voyages to Japan, Formosa, Cambodia and Palembang, he was chosen by the governor general of the Dutch East Indies, Antonio van Diemen, to command in 1642 the most ambitious of all Dutch voyages for the exploration of the southern hemisphere.

**Tasman's Voyage 1642–43.**—By 1642 Dutch navigators had discovered discontinuous stretches of the western coast of Australia, but whether these coasts were continental and connected with the hypothetical southern continent of the Pacific remained unknown. Tasman was to answer this problem, following instructions based on a memoir by Frans Jacobszoon Visscher, his chief pilot. He was to explore the Indian ocean from west to east, south of the ordinary trade route, and, proceeding eastward into the Pacific (if this proved possible), to investigate the practicability of a sea passage eastward to Chile, to rediscover the Solomon Islands of the Spaniards and to explore New Guinea.

Leaving Batavia on Aug. 14, 1642, with two ships, the "Heemskerck" and "Zeehaen," Tasman sailed to Mauritius (Sept. 5–

Oct. 8), then southward and eastward, reaching his most southerly latitude of 49° S. in about 94° E. Turning north he discovered land on Nov. 24 in 42° 20' S. and he skirted its southern shore naming it Van Diemen's Land (now Tasmania). A council of officers on Dec. 5 decided against further investigation, so he missed the opportunity of discovering Bass strait. Continuing eastward, he sighted on Dec. 13, in 42° 10' S., the coast of South Island, New Zealand, and explored it northward, entering the strait between North Island and South Island but supposing it to be a bay. He left New Zealand on Jan. 4, 1643, at North cape under the impression that he had probably discovered the west coast of the southern continent, which might be connected with the "Staten Landt" discovered by W. C. Schouten and J. Le Maire south of South America: hence the name of "Staten Landt" which Tasman gave to his discovery in honour of the states-general.

Convinced by the swell that the passage to Chile existed, Tasman now turned northeast and on Jan. 21 he discovered Tonga and on Feb. 6 the Fiji Islands. Turning northwest, the ships reached New Guinea waters on April 1 and Batavia on June 13, 1643, completing a ten months' voyage on which only 10 men had died from illness. Tasman had circumnavigated Australia without seeing it, separating it from the hypothetical southern continent.

The council of the company decided, however, that he had been negligent in his investigation of the lands discovered and of the passage to Chile. They sent him on a new expedition to the "South Land" in 1644.

**Tasman's Voyage 1644.**—Tasman's instructions ordered him to establish the relationships of New Guinea, the "great known South Land" (western Australia), Van Diemen's Land and the "unknown South Land." He sailed from Batavia on Feb. 29, steering southeast into Torres strait, which he mistook for a shallow bay, coasting the Gulf of Carpentaria and then following the coast of Australia to 22° S.

Although he was rewarded with the rank of commander and was made a member of the Council of Justice of Batavia, his second voyage was also a disappointment to the company because it had failed to reveal lands of potential wealth. In 1647 Tasman commanded a trading fleet to Siam, and in 1648 a war fleet against the Spaniards in the Philippines. He had left the company's service by 1653 and died probably before Oct. 22, 1659, and certainly before Feb. 5, 1661.

**BIBLIOGRAPHY.**—The standard authorities are J. E. Heeres (ed.) *Abel Janszoon Tasman's Journal* (1898); R. Posthumus Meyjes (ed.) *De Reizen van Abel Janszoon Tasman en Franchoyz Jacobszoon Visscher* (1919). See also R. H. Major, *Early Voyages to Terra Australis*, Hakluyt Soc. (1859); J. B. Walker, *Abel Janszoon Tasman, his life and voyages* (1896); J. C. Beaglehole, *The Discovery of New Zealand* (1939); G. C. Henderson, *The Discoverers of the Fiji Islands*, pp. 3–99 (1933). The first published account in England of Tasman's voyage of 1642–43 (a translation from the Dutch of Arnoldus Montanus, 1671) appeared in John Ogilby's *America*, pp. 653–661 (1671). 1682 Robert Hooke published in his *Philosophical Collections*, no. 6, pp. 179–186, the first English translation of D. R. van Nierop's *Reizen oeffeningen* (1674), comprising extracts from a journal of the voyage. (H. M. Ws.)

**TASMANIA**, the smallest state of the Commonwealth of Australia, comprises the large island of Tasmania and numerous smaller islands lying to the south of the southeastern edge of the continental mainland. Tasmania, which is separated from the mainland by the Bass Strait, a 150-mi. (240-km.)-wide stretch of shallow sea (30–40 fathoms), is a shield-shaped island with a maximum length of 180 mi. (290 km.), a maximum width of 190 mi. (306 km.), and an area of 24,450 sq. mi. (63,326 sq. km.). The total area of the state, including King Island and the Furneaux Group in the Bass Strait, and Macquarie Island, about 850 mi. (1,370 km.) SE of Tasmania, is 26,215 sq. mi. (67,897 sq. km.), or less than 1% of the area of Australia. The state capital is Hobart.

#### PHYSICAL GEOGRAPHY

**Geology.**—Precambrian rocks outcrop in an axial, meridional belt and in anticlinal areas in western, northwestern, and northern Tasmania. They consist of an association of quartzite, schist, gneiss, and amphibolite in the axial belt and in the cores of anti-

MAJOR CITIES AND PHYSICAL FEATURES OF TASMANIA

sandstone, siltstone, and limestone during the later part of the Lower Devonian and the earlier part of the Middle Devonian. Movements took place during deposition but the main folding occurred a little later during the Middle Devonian. Extensive granitic intrusions followed the folding and caused the formation of metallic mineral deposits (copper, lead, zinc, tin, tungsten, and gold). Continental glaciation in the Upper Carboniferous or Lower Permian resulted in the deposition of tillite and was followed by a marine transgression producing sandstone, shale, and limestone with pebbles and glacial erratics and rich in fossils. The Triassic comprises sandstone and siltstone with plants, fish, amphibians, and reptiles, followed by claystone, tuffaceous sandstone, and coal seams. The Permo-Triassic sequence is intruded by thick sheets, a few cone sheets, and some dikes of dolerite of Middle Jurassic age (about 165,000,000 years old). The land surface was penetrated in the Late Mesozoic and broken by normal faulting in the early Paleocene, resulting in block mountains separated by north-north-westerly trending grabens. The grabens filled quickly with gravels, sands, silts, clays, and some peats to a maximum thickness of 1,000 ft. (300 m.). The Bass Strait depression was occupied during Oligocene and Miocene times by a sea which encroached

beyond the present shores to deposit thin sands and limestones which are richly fossiliferous. Tasmania was glaciated during the Pleistocene with the development of minor ice caps, valley glaciers, and small mountain glaciers. Bass Strait was almost drained by a retreat of the sea, but a rise in sea level after the glaciation again flooded the strait, together with the estuaries of the Tamar, Derwent, Huon, and Gordon rivers.

(M. R. Bs.)

**Physical Features.**—Tasmania, an island of plateaus, plateforms, and rugged ranges, exhibits the most spectacular mountain scenery in Australia. Along the west coast are remarkably even, deeply incised platforms up to 1,500 ft. (460 m.) in height, upon which stand isolated monadnocks. Detached portions are King Island and the Furneaux Group. Eastward lie discontinuous rugged ranges of Paleozoic fold structures rising above 4,000 ft. (1,200 m.), and in the northwest a basalt plateau sloping northward from 2,000 ft. to a cliff coast. The northeastern platforms are generally below 500 ft., but to the south lie the geologically complex and maturely dissected northeastern highlands (4,600 ft. [1,400 m.]). The southwestern portion is the Ben Lomond block, a flat-topped dolerite mesa (more than 4,000 ft.) with residual tors (up to 5,010 ft. [1,527 m.]). Westward lies the Midland rift valley, floored partly by soft Miocene lake sediments and drained by mature meandering rivers. In the centre stands the high, relatively undissected, dolerite central plateau, bounded northeast by a fault scarp, west by glacial troughs, and sloping southward from 4,000 to 2,000 ft. Its surface includes 5,000 small rock-basin lakes of glacial origin in the west and a few large, very shallow lakes of unknown origin in the east. To the west and south lies the high

chinal structures and a presumably younger association of slate, quartzite, dolerite (700,000,000 years old), and minor dolomites best developed in the northwest and west and overlain unconformably by a dolomitic succession in a north-northwesterly trending zone from King Island to southeastern Tasmania. Younger Precambrian rocks are the hosts of major tin deposits at Mt. Bischoff and Renison Bell and of scheelite on King Island. A thick (13,000 ft. [4,000 m.]) succession of unfossiliferous siltstones which may be Lower Cambrian overlies the Precambrian rocks in western Tasmania and a thick (10,000 ft. [3,000 m.]) pile of dominantly acid volcanic rocks which may also be Lower Cambrian borders the axial, meridional geanticline of Precambrian rocks. Fossiliferous Middle and Upper Cambrian rocks at least 10,000 ft. thick are widespread in northern and western Tasmania. The Cambrian rocks contain the most important ore deposits in Tasmania, especially in areas of schisted volcanic rocks. The Cambrian rocks were gently folded (probably late in the Upper Cambrian) and small masses of granite intruded especially around the margin of the geanticline. The Ordovician cycle of deposition began with a coarse siliceous conglomerate followed by sandstone (Lower Ordovician), siltstone, and about 5,000 ft. (1,500 m.) of richly fossiliferous limestone, the top of which is Upper Ordovician. Silurian and Lower Devonian rocks which covered most of the island comprise about 5,200 ft. (1,600 m.) of richly fossiliferous quartzite, slate, and a little limestone in the western half of the island and at least this thickness of poorly fossiliferous siltstone and graywacke in eastern Tasmania. Folding began in the Lower Devonian and initiated a small new basin of deposition in western Tasmania, which received about 2,000 ft. (600 m.) of

dissected western edge of the dolerite sills, with the highest point in Tasmania (Mt. Ossa, 5,305 ft. [1,617 m.]), and, in the Ducane Range, the only extensive area of glaciated alpine scenery in Australia. Southeastern Tasmania comprises low dissected dolerite sills with fault-determined basins, ranges, and troughs.

The coastline owes much to faulting and postglacial drowning. Silt deposition and the growth of sandpits and tidal marshes, aided by a recent emergence of about 70 ft., are widespread, but particularly marked in the north. The southeast, with its deep Huon and Derwent rias and drowned interfluvial summits tied together into peninsulas, is one of the finest drowned coastlines in the world.

**Climate.**—Tasmania lies in the westerly wind belt of the mid-latitudes. Local surface-controlled winds, gusty and variable in direction, give clear skies, abundant sunshine, and a wide daily temperature range. Except in upland areas, monthly temperatures range from 15.6° to 18.3° C (60° to 65° F) in summer and from 7.2° to 10° C (45° to 50° F) in winter, the east coast being about 2° C warmer than the west coast because of modifying warm (north) and cool (south) sea currents, respectively. In general, rainfall derives from southern maritime air masses and decreases eastward. It exceeds 100 in. (2,540 mm.) a year on the western ranges, averages 50–30 in. (1,270–762 mm.) along the north coast, and 30–20 in. (762–508 mm.) in the Midlands. Except in the east and southeast, where occasional heavy spring rains derive from northern maritime air masses, there is a pronounced winter maximum. In summer, northern continental air masses occasionally bring Tasmania hot, dry northerly winds for short periods.

**Soils.**—Tasmania, with its rugged relief, humid climate, and forest vegetation, is characterized by gray, sandy podsols, interspersed with extensive tracts of shallow immature soils. In superhumid highland areas and on the western platforms podsols are replaced by peats, and in the subhumid Midlands and southeast, by brown earths and black soils. Alluvial soils are significant only along the middle Derwent. Fertile red loams derived from basalt occur in the northwest and locally in the northeast. (P. Str.)

**Vegetation.**—The wide range in physical conditions gives Tasmania a great variety of habitats for plants. The major plant communities are sclerophyll forest (dominated by eucalypts), temperate rain forest, austral montane, and sedge moor and heath. Areas of these and of coastal stretches are included in about 1,000 sq. mi. (2,590 sq. km.) of eight national parks and other proclaimed reserves. Sclerophyll forest is characteristic of regions having an annual rainfall of less than 60 in. (1,524 mm.). The fine forests in the 30–60 in.-rainfall areas have been extensively exploited for timber and for the paper industry; they have also suffered from destructive fires. Species of economic importance are *Eucalyptus regnans*, *E. obliqua*, *E. gigantea*, and *E. globulus*. In the drier central and eastern parts of the state a savanna woodland occurs in which *E. pauciflora* is dominant; she-oaks (*Casuarina* species) and wattles (*Acacia* species) are conspicuous. Temperate rain forest, which develops in superhumid areas, is characterized by myrtle (*Nothofagus cunninghamii*), an evergreen timber tree that grows to a height of 100 ft. (30 m.), and by southern sassafras (*Atherosperma moschatum*). This community contains several endemic conifers valuable as timber although no longer plentiful—the Huon pine (*Dacrydium franklinii*), King William (Billy) pine (*Athrotaxis selaginoides*), and celery-top pine (*Phyllocladus aspleniifolius*). Myrtle and other rain-forest species, including a tree fern, *Dicksonia antarctica*, also grow as an understory in wet sclerophyll forests. In certain areas, particularly in the forests of the south and southwest, an almost impenetrable thicket known as horizontal scrub develops. This is due to the growth of a small tree called horizontal (*Anodopetalum biglandulosum*). The slender trunk of the tree falls over under its own weight, and from it branches arise that behave in the same way. In both sclerophyll and rain-forest regions large areas of acid, waterlogged soil support a sedge moor characterized by button grass (*Gymnoschoenus sphaerocephalus*). In the wettest sections this sedge forms large tussocks 2–6 ft. high, but elsewhere other members of the family Cyperaceae and of the Restionaceae are dominant. On the mountain plateaus are found many plants having subantarctic affinities. These include *Nothofagus gunnii*, Tasmania's only deciduous tree

or shrub, and certain cushion plants. The latter are perennial evergreen dicotyledons with numerous branches bearing small stiff leaves closely overlapped; a cushion plant forms a firm mound often 3 ft. (1 m.) or more in diameter.

**Animal Life.**—Native mammals comprise 2 species of monotremes and 19 species of marsupials. Of the latter, 7, including the Tasmanian devil, the thylacine or wolf, and wombat, are endemic. Nearly half of the Tasmanian marsupials are carnivores or omnivores (whereas in mainland Australia herbivores preponderate). Several species are locally abundant and 2, Bennett's wallaby and the pademelon, are exploited for fur and meat. The 2 monotremes, or egg-laying mammals, which are wholly protected, are widespread; they are the echidna, or spiny anteater, and platypus. The latter occurs in many freshwater lakes and streams. Birds characteristic of the open forest include the honeyeaters and wattlebirds (family Meliphagidae), and also parrots and cockatoos. The fairy penguin nests along the coasts. The Tasmanian mutton bird is of economic importance. This migratory bird travels between southeastern Australia and the Aleutian Islands; its large breeding grounds are on the islands of Bass Strait. Among the reptiles there are three species of venomous snakes. Native freshwater fish include representatives of the families Galaxiidae and Haplochitonidae, the distribution of which is confined to cool temperate regions of the Southern Hemisphere. Certain invertebrates are of special interest, particularly 2 freshwater shrimps (*Anaspides tasmaniae* and *Paranaspides lacustris*), which show primitive features in anatomical structure. (W. M. C.)

## HISTORY

Tasmania, or Van Diemen's Land as it was called until 1853, was discovered in 1642 by the Dutch navigator Abel Tasman (q.v.). It was named after Antonio van Diemen, the governor-general of the East Indies at whose command Tasman sailed. Further exploration awaited the French and British navigators Marion Dufresne (1772), Tobias Furneaux (1773), James Cook (1777), William Bligh (1788 and 1792), Bruni d'Entrecasteaux (1792–93), John Hayes (1793), George Bass (1798), Nicolas Baudin (1800 and 1802), and Matthew Flinders (1798 and 1802). The first British settlement was made at Hobart (1804) and was followed by another that was to become Launceston (1806); most of the first settlers, both free and convict, were transferred from Norfolk Island. The settlement, under resident lieutenant governors, was governed from New South Wales. Free immigrants were attracted by land grants and by the development of the sheep and whaling industries. Van Diemen's Land was made a colony by order in council in 1825, and henceforward its government was practically separated from that of New South Wales and until 1850 was exercised through nominated executive and legislative councils. In this period, despite the depredations of the outlaw bushrangers and the "black war," which virtually extinguished the aboriginal people, great material progress was made. In 1828 the total white population was 17,000, of whom 7,500 were convicts under restraint, though a majority were assigned as servants to free settlers. Grain was exported regularly to New South Wales, while rising wool prices brought general prosperity and stimulated much speculation in land. The adoption of the probation system for convicts in 1840 marked a change in British policy on transportation, depriving free settlers of assigned servants and transforming the colony into a penal settlement. The influx of population was rapid until 1847, growing to 70,000, but the ratio of free to unfree was reversed. In the late 1840s the boom gave way to an economic depression, and the colonial government faced a deficit, which local opinion attributed to the cost of police and jails. Belatedly the home authorities offered some relief but not before public opinion was roused to demand representative institutions and the cessation of transportation of British convicts. Representatives were first elected to the Legislative Council in 1851, and the transportation policy ceased in 1853. The constitution was settled more definitely in 1856 with the election of a two-chamber parliament and the appointment of the first responsible ministry.

The gold discoveries in Victoria in 1851 caused inflation and labour shortage in Tasmania, and the economy was unable to

support the strain. The whaling industry declined and with it ship-building. The adoption of a protectionist policy by Victoria injured Tasmanian manufactures. After 1857 a prolonged depression, lasting 25 years, was marked by deficits, reduction in services, opposition to all forms of taxation, political feuds, and frequent changes in ministries. Under competition from continental Australia, wheat production declined to its present insignificance.

After 1880 economic conditions improved, largely because mining industries were opened up in the west and northeast. The hardwood forests were exploited, and fruit growing in the south became the basis of small manufacturing and export industries. Railways, roads, and harbour facilities were developed, while relative political stability was achieved, particularly during the Fysh ministry (1887-92). After the recession following on the failure of the Bank of Van Diemen's Land in 1891, there was from 1894 to 1899 a slow recovery during Sir Edward Braddon's ministry. In the 1890s a majority of Tasmanians supported the movement that ended in 1901 with Australian federation (*see AUSTRALIA, COMMONWEALTH OF: History*).

Economic development slowed down after 1910 as the mining boom passed, and during the next 25 years Tasmania was relatively depressed, the worst years being 1922-26 and 1931-35. Population grew slowly, the birth rate fell, and the exodus of the young and more vigorous people was resumed.

State politics entered a new phase with the founding of the Labor Party in 1903. Labor first took office in 1909 and was again returned to power in 1914. From that time both the Labor and the Liberal (Nationalist) parties sponsored social and industrial legislation. All the administrations faced financial difficulties, which were not resolved until in 1933 the commonwealth government set up the Grants Commission, through which special financial assistance is given to the state.

A Labor government was formed in 1934 and continued without a break to govern the state up to the mid-1960s. During this period secondary industry, based on hydroelectric power, grew rapidly in many parts of the state.

(W. A. Ty.)

## POPULATION

For more than a century Tasmania experienced a steady drift of population to the mainland, and only two periods of net immigration have been recorded: from 1875 to 1905 during the mining boom and from 1947 to 1961. The population increased from 115,705 at the 1881 census to 172,475 in 1901, to 213,780 in 1921. In 1947 it was 257,078; in 1954, 308,752; and in 1961, 350,340. Tasmania has long had a high rate of natural increase; during 1956-60 the crude birth rate was 25.45, which compared with the rate of 22.59 for Australia.

At the 1961 census Hobart was the eighth largest city in Australia, with a metropolitan population of 115,932. Launceston had 56,721. Other towns with a population of more than 5,000 were Burnie (14,201), Devonport (13,068), Ulverstone (5,962), and New Norfolk (5,445).

## ADMINISTRATION AND SOCIAL CONDITIONS

**Administration.**—The state of Tasmania is administered by a governor, who is the direct representative of the British sovereign, and by a Parliament comprising a Legislative Council and a House of Assembly. Election is by the Hare-Clark System of a single transferable vote and with the obligation to record at least three preferences. The state is also represented in the Senate and House of Representatives of the commonwealth Parliament. Local government is by 3 city councils (Hobart, Launceston, and Glenorchy), 2 government commissions (Clarence and Kingsborough), and 44 municipal councils.

**Education.**—The state Education Department controls almost 300 schools comprising infant, primary, and (in country towns) area schools, high schools (including comprehensive high schools), and district schools. Attendance is compulsory between the ages of 6 and 16. Special provision has been made for mentally retarded children and for those with physical handicaps. Nonstate, fee-charging schools total more than 60 and contain less than one-fifth of all children attending school. Most of the nonstate schools

are Roman Catholic, Church of England, or are affiliated with other religious denominations; they receive no state assistance. Teacher training is provided by teachers' colleges in Launceston and Hobart and by the faculty of education at the University of Tasmania. The university (founded 1890) had in the 1960s a teaching staff of about 140, with more than 2,000 students, and awarded degrees in arts, commerce, law, science, engineering, agriculture, and medicine.

**Health.**—Hospital services are provided by the state, as well as by private (but subsidized) institutions maintained by religious denominations and public bodies. Public hospital services include general hospitals at Hobart, Launceston, Latrobe, and Burnie, maternity hospitals at Hobart and Launceston, 16 district hospitals, and 12 district nursing centres. In addition, Hobart and Launceston have special institutions for the care of crippled children, tuberculosis patients, and the aged and invalid (also at Wynyard); New Norfolk has a mental hospital. State medical officers are provided in 14 municipalities that cannot support a private practitioner. The state also provides a child welfare service (for expectant mothers and infants under two years) and school medical and dental services. Annual X-ray examinations for adults are compulsory by law.

**Social Services.**—Various social service benefits are payable under commonwealth legislation, notably child endowment (family allowances), maternity allowances, unemployment and sickness benefits, invalid pensions, allowances for wives and children of invalid pensioners, and age and widows' pensions. Except for maternity allowances and child endowment, benefits are subject to residential qualifications and a means test.

**Living Conditions.**—There are no great extremes of wealth or poverty in Tasmania; the more prosperous sections of the community comprise ranchers, professional workers, and retailers. Home ownership is a fundamental feature of Tasmanian life. The numerical importance of small and medium property owners is reflected in the relatively conservative tendency of both political parties. The work force of the larger industrial, mining, and public utility undertakings is organized in well-established labour unions. The minimum wages and conditions of Tasmanian employees are regulated either by awards of the Commonwealth Arbitration Court or by state wages boards.

## THE ECONOMY

**Agriculture.**—Agriculture is restricted by rugged relief and a superhumid climate to a belt through the north and east. Level, cultivable land is nowhere extensive. To overcome the disabilities of small-scale production and distance from markets, farmers tend to diversify farm enterprises, to concentrate on such specialties as fruit, hops, stud stock, and superfine wool, and to intensify their methods. Specialized dairying for butter manufacture occurs only in the far northwest and far northeast. Elsewhere in the north, mixed dairying (for butter) and vegetable growing (chiefly potatoes and peas) are dominant. Apples and pears are grown in the Tamar and Mersey valleys. Sheep farming, with some subsidiary beef-cattle raising and cereal cultivation (mostly oats but also soft wheat and barley), typifies the Midlands, but toward the north and south fat lambs increase in importance relative to wool. The central plateau is used for summer grazing. In the southeast hops are a specialty of the irrigated alluvial terraces of the middle Derwent, small fruits of the hills west of the lower Derwent, and stone fruits east of the lower Derwent. Apples and pears are specialties of the Huon Valley, the d'Entrecasteaux Channel shores, and the Tasman Peninsula.

**Fisheries.**—Productivity is limited by a narrow continental shelf and by the low plankton content of the subtropical east Australian current. Fishing is mostly confined to the north and east coasts. The principal species caught are barracouta and crayfish, but snapper or school shark and gummy shark are also taken, primarily for their liver oil. Scallops are dredged chiefly from the d'Entrecasteaux Channel, and whitebait is taken in many Tasmanian rivers. Salmon and some mackerel, flounder, and mullet are also caught. Tuna is increasing in importance. Like agriculture, fisheries rely on export markets, chiefly Melbourne and Sydney.

**Mining.**—Tasmania produces a variety of minerals, mostly nonferrous and ferroalloy metals. The western ranges yield mainly copper (about 15,000 tons a year), zinc (38,000 tons), and lead (12,000 tons), while the northeastern highlands yield mainly tin (1,000 tons) and tungsten (500 tons). Copper is derived largely from the West Lyell opencut mine near Queenstown, silver, gold, and pyrites being by-products. At Rosebery the underground Rosebery and Hercules mines furnish mainly zinc but also lead and copper. West of Rosebery, tin is mined at Renison Bell. In the northeast the largest tin mine is the Aberfoyle at Rossarden and the largest tungsten mine at Storey's Creek. Alluvial tin with some gold is extracted at Derby and elsewhere. Important scheelite deposits occur on King Island. Triassic coal, subbituminous with a high ash and sulfur content, is mined (about 200,000 tons a year), chiefly near St. Marys. Limestone, widely distributed throughout the state, is quarried (about 350,000 tons a year) largely for cement production at Railton, but also for metallurgical purposes, carbide manufacture, and agricultural lime.

**Manufacturing Industries and Power Supply.**—Secondary industry, like agriculture, is handicapped by the absence of a large local market and by shipping difficulties but has the advantage over the rest of Australia of cheaper power (wholly hydroelectric). The state has therefore concentrated on electrometallurgical and electrochemical specialties and on processing its own primary products.

Tasmania has more than two-thirds of Australia's hydroelectric plant and about one-half of its potential resources. Apart from the Trevallyn Station on the Tamar River near Launceston, all development, which is undertaken by the state-owned hydroelectric Commission, has been confined to the central plateau. Industries using bulk power supplies include the electrolytic refinery at Risdon, which treats zinc concentrates from Broken Hill and Rosebery, the aluminum reduction works at Bell Bay near George Town, the pulp and paper mills at Boyer near New Norfolk and at Burnie, and the carbide works at Electra south of Hobart.

Other important industries include the manufacture of woolen yarn (Launceston), other textile goods (Launceston and Devonport), chocolate (Claremont, near Hobart), hardboard (Burnie), plywood (Somerset), and titanium pigments (near Burnie). Numerous factories process fruit, vegetables, dairy produce, and fish.

**External Trade.**—Tasmania lies within the Australian customs area. Interstate trade, of which one-sixth of the exports and one-quarter of the imports are carried by air, accounts for nearly three-quarters of Tasmania's exports and four-fifths of its imports. Of total exports, primary products, such as greasy wool, fresh fruit, potatoes, mineral concentrates, hides and skins, peas, hops, and fish, furnish more than one-third. Secondary products include zinc ingots, newsprint and writing papers, woolen manufactures, scoured wool, sawn timber, copper, canned fruit and vegetables, silver-lead, butter, tungsten, tin, jam, carbide, and confections. Apart from raw wool (grades not produced in Tasmania), imports are mainly producers' materials and manufactured consumers' goods, principally machinery, motor vehicles, petroleum products, hardware, textiles, clothing, and foodstuffs. Hobart handles twice as much sea trade as Launceston but is less important than Launceston for air trade.

**Finance.**—Tasmania has benefited considerably from federal grants paid annually in accordance with the recommendations of the Commonwealth Grants Commission and from substantial tax reimbursement grants paid by the commonwealth government on condition that no taxation is levied by the state on incomes received by persons or companies. These grants have reduced the adverse effects of Tasmania's relative disadvantage in taxable capacity and have made possible somewhat higher standards, especially in education and health services.

**Transportation and Communications.**—Internal transport is coordinated by the Transport Commission, which operates most of the 800 route miles (1,290 km.) of railway (3 ft. 6 in. gauge) (1.07 m.) and licenses and operates road-passenger and road-freighting services. Less than half the main road mileage has been paved. Radio and television stations, both national and commercial, serve the main cities. Transportation to the Australian main-

land is provided by cargo and passenger ships, by "drive-on" ferries (for motor vehicles), and by frequent air services.

**TASMANIAN DEVIL** (*Sarcophilus harrisii*), a pouched mammal, or marsupial (*q.v.*), of the family Dasyuridae. It is now restricted to Tasmania but is in no danger of extermination. The condition of skulls and other bones found in Victoria suggests that this animal inhabited the Australian mainland until recently. It is terrestrial and heavily built, resembling a small bear or badger (hence the specific name of *ursinus*, or bearlike, given it when first observed). From nose to tail-tip it measures about 3½ ft. (about 107 cm.). The general colour is black tinged with brown; chest, shoulder, and rump patches are white. Its fierce expression, strength, and harsh, husky cough or snarl have earned the animal its name of devil or native devil and its exaggerated reputation for ferocity. The mating season is in March and April, the young being born in May. Their variable diet consists of small mammals, birds, lizards, and carrion. (Jo. E. H.)

**TASMANIANS**, an extinct Negritoid people once found in Tasmania (*q.v.*). Male average height was about 5 ft. 6 in. (1.7 m.); they had flat noses and wide nostrils (the nasal index being the highest on record), shorter and broader heads than mainland Australian Aborigines, full, fleshy lips, bushy beards, and very curly to woolly hair.

Two main theories of their origin are held: (1) They formed the original population of eastern coastal Australia; then, yielding to Australoid immigrants, they crossed into Tasmania. (This view implies a land corridor [available 12,000 years ago] or shorter stretches of ocean and also winds and currents in the opposite direction to those now prevailing.) (2) They drifted to Tasmania in canoes or rafts from the New Hebrides region where there are similar Negritoid types; winds and currents favour such voyages as well as possible landings on the Queensland coast.

The most reliable assessment of Tasmanian population before European settlement in 1803 is 2,000 or less; the last full blood is recorded as having died in 1876. This peaceful people became fearful and resentful when faced with dispossession and with cruelty on the part of some European convicts and settlers. By 1826 the clash was officially recognized; by 1831 (to prevent their extermination by the settlers) they were removed first to Gun Carriage Island and then to Flinders Island, where, in spite of care, they languished and died out.

The Tasmanians were organized as five tribes, each with its own dialect or language. They usually traveled in small groups, gathering food and hunting with sticks and clubs; they had neither spear-thrower nor boomerang. They held corroborees, cremated the dead, scarred and red-ochred their bodies, and engraved lines and circles on rocks. See also AUSTRALIAN ABORIGINES.

**TASSO, TORQUATO** (1544-1595), the greatest Italian poet of the late Renaissance and author of the epic *Gerusalemme liberata*, was born in Sorrento on March 11, 1544, the son of Bernardo, also a poet and author of the long and romantic *Amadigi* (1560), and Porzia de' Rossi. His childhood was overshadowed by family misfortunes and when, in 1552, Bernardo was banned from the kingdom of Naples, Torquato followed him into exile. Four years later, while father and son were staying in Rome, his mother died. His father's exile and the somewhat mysterious death of his mother struck the imagination of the young Torquato. In 1557 he went with his father to Pesaro and Urbino and there he had his first experience of court life. In 1559 they were in Venice and in 1560 Torquato went to Padua to study law, philosophy and rhetoric, a study which he continued in Bologna between 1563 and 1564, and then again in Padua until 1565. In Padua he met the philosopher Sperone Speroni and became aware of the subtleties of the classicist theory of poetry. He became a friend of Scipione Gonzaga, the future cardinal, and entered the Academy of the Etereî which Gonzaga had founded. In Padua he also composed his first epic, the *Rinaldo* (publ. 1562), and his lyrical poems to Lucrezia Bendidio and Laura Peperara.

Toward the end of 1565 Tasso entered the service of Luigi Cardinal d'Este and went to live in Ferrara, where, as a young poet admired by the court, he passed the happiest period of his life. In the Ferrarese academy he expounded his *Conclusioni d'Amore* (publ. 1581) according to the Renaissance tradition of love treatises. From Paris, where he went with the cardinal in 1570, he wrote an interesting letter which shows him as a subtle political observer. In this period he composed his complimentary verses for the duke's sisters, Lucrezia and Leonora d'Este, and his love lyrics for Laura Peperara and Eleonora Sanvitale. He associated with men of letters such as Guarini and Giambattista Pigna, and participated in the life of the court—his pastoral drama *Aminta* (publ. 1580) was performed on the island of Belvedere in the summer of 1573. In 1574 he began his tragedy *Galealto re di Norvegia* and in April 1575 he completed the *Gerusalemme liberata* which he had begun a few years earlier. In Jan. 1572 he had entered the service of Duke Alfonso II, with a high salary and without heavy duties.

During the last months of 1575, however, this happy period of his life began to be overshadowed by the psychological disturbances which tormented him for the rest of his life. Before publishing the *Gerusalemme*, he asked many people for advice, including Gonzaga, the theologian Silvio Antoniano, Speroni and the versifier Pietro Angeli da Barga. The critical observations for which he had asked humiliated and irritated him, and he was deeply concerned with most of the moral and poetical problems raised by his advisers. At this time Tasso developed an acute egotism accompanied by a persecution mania, which showed itself in such episodes as his throwing a knife at a servant whom he suspected of spying on him, and in his frequent, restless

travels. From Sorrento, where he stayed with his sister in 1577, he went to Rome, and thence, in April 1578, again to Ferrara. At the beginning of July he moved to Mantua, and then to Padua, Venice, Pesaro and, finally, to Turin, as a guest of the marquis Filippo d'Este. In Feb. 1579 he returned to Ferrara during the festivities for the wedding of the duke with Margherita Gonzaga and, thinking himself neglected, he flew into a rage. The duke had him arrested, chained and imprisoned in the Ospedale di Sant'Anna, where he remained for seven years. That this was due to his alleged love for Leonora, the duke's sister, must be considered a legend. It is more likely that the real cause of the duke's severity was the danger Tasso represented to the Este court, where, even after the exile of the duke's mother, Renée of France, a sympathizer of Calvin, there survived sympathy for Calvinistic reform. Accusations of heresy by Tasso could have helped the pope in his anti-Este policy.

During his seclusion in Sant'Anna the poet remained in touch with the outside world through his correspondence and the many occasional poems which he wrote, and he also composed most of his *Dialoghi* and the *Apologia* in defense of his epic. Finally, in July 1586, thanks to the intervention of Father Angelio Grillo and of Vincenzo Gonzaga, prince of Mantua, Tasso was allowed to leave Sant'Anna.

In Mantua, where he received a warm welcome, he finished his tragedy *Galealto* under the new title *Torrismondo* (publ. 1587). In Oct. 1587 he fled from Mantua and took refuge in Rome, where he spent most of his last years as the guest of Cardinal Gonzaga and then of the cardinals Pietro and Cinzio Aldobrandini, to whom he dedicated in 1593 his recast epic *Gerusalemme conquistata*. He went for short periods to Florence in 1590, to Mantua in 1591 and to Naples, where he hoped to recover his mother's dowry, in 1588, 1592 and 1594. In Naples he was the guest of G. B. Manso who eventually became the author of one of the first biographies of Tasso, and there he wrote his religious poems, the *Monte Oliveto* (publ. 1605) and the *Sette giornate del mondo creato* (publ. 1600-05), besides a fragment of the *Vita di San Benedetto* and his last dialogues. In Rome he composed *Le lagrime di Maria Vergine* (1593) and *Le lagrime di Gesù Cristo* (1593). During his last years his illness and discontent continued, despite the fact that he was then receiving many honours and proofs of friendship—in 1594, plans were being made for his poetical coronation in Rome. By then he was tired and no longer interested in fame. In March 1595 he fell ill and asked to be transferred to the convent of Sant'Onofrio in Rome, where he died on April 25, 1595.

**Tasso's Works.**—When Tasso composed his epic *Rinaldo* (publ. 1562), relating the youth of the hero in 12 cantos in ottave, he paid little attention to the Aristotelian rules: the poem reveals his technical ability, but not as yet his poetical genius. In comparison the *Aminta*, composed ten years later, is already a masterpiece. This pastoral drama reflects the ephemeral period of happiness which Tasso enjoyed at the Ferrarese court. Technically it stands halfway between the eclogue in dialogue form and the melodrama, and is full of literary reminiscences of Theocritus, Moschus, Achilles Tatius, Virgil, Ovid, Propertius, Claudian and Nemesianus, as well as of Petrarch, Politian, Jacopo Sannazzaro, Ariosto, Pietro Bembo and others. The allusions to the court are of great delicacy and the result is a work of extreme literary preciousness. The *Aminta* has been defined as the idealization of court life. The inspiration of the poet is lyrical rather than dramatic and in this respect the work ranks with his sonnets, canzoni and madrigals.

The *Rinaldo*, the *Aminta* and the *Rime* (publ. 1581-87) are a prelude to the composition of the *Gerusalemme liberata*. The idea of an epic poem on the conquest of Jerusalem arose in Tasso's mind at a very early date (the first drafts belong to his Venetian and Paduan period), and grew during his stay at Ferrara; the work was completed in 1575. The subject and structure of the poem offered him the possibility of expressing his complex nature, while responding to a taste that was typical of his time. The *Liberata* resumes and develops a Renaissance literary tradition: the desire to renew the classical epic and to reconcile it with the new trends of the Counter-Reformation. While engaged in composing the

TASSO; PORTRAIT BY F. ZUCCHERI, 1594

*Liberata*, Tasso wrote his *Discorsi dell'arte poetica* (rewritten later as *Discorsi del poema eroico*, publ. 1594), in which he expounded his qualified acceptance of the Aristotelian rules (for instance, unity of action was not to exclude a variety of episodes) while in fact upholding the rights of poetry. In the *Liberata*, Tasso narrates the actions of the Christian army led by Geoffrey of Bouillon during the last months of the first crusade, culminating in the conquest of Jerusalem and the battle of Ascalon. To the principal action he adds a number of episodes, including (in deference to the d'Este family) the story of Rinaldo d'Este, his rebellion, his love for the pagan Armida and his repentance and decisive participation in the final battle. Tasso also adds the story of the love of the Italian Tancred for the beautiful Saracen Clorinda, whom Tancred kills without recognizing her; the secret passion of Erminia, princess of Antioch, for Tancred; and the intervention of supernatural forces in favour of Aladino, king of Jerusalem. These episodes give him the opportunity of expressing the different aspects of his inspiration but his lyricism predominates even in his epic work. The language is lyrical in the Petrarchan tradition, and lyrical, too, is the rhythm of his hendecasyllables and of his *ottave*.

The poetical novelty of the *Liberata* aroused violent criticism, to which Tasso replied in 1585 with his *Apologia*. Tasso's prose works (*Dialoghi* and *Lettere*) show his ability as a stylist who, while following classical models, achieves a modern form in which classical and popular patterns are admirably blended. The works of his last years have no poetical significance: the *Conquistata*, in which he tries to rewrite his epic according to strict moral and rhetorical preconceptions, is a document of the poet's decline, while the tragedy *Torrismondo* shows passages of real poetry only where the poet allows his lyrical inspiration to express itself.

Tasso's life soon became the subject of a legend concerning his alleged love for the princess Leonora and his mysterious madness. The latter is described as simulated in Alessandro Guarini's *Farnetico savio* (1610), while Tasso's love affairs are narrated in the early biographies by G. P. D'Alessandro (1604) and G. B. Manso (1621). This legendary tradition lasted until the 19th century, in spite of the doubts already expressed in the 18th century by G. Tiraboschi and P. A. Serassi. During the romantic period Tasso's life became a symbol of the poet's life and the subject of novels and dramas (of which the most famous is Goethe's *Torquato Tasso*, 1790). Later criticism, while rejecting legendary details of Tasso's life, concentrated on determining the pathological background of his genius and on underlining the moral weakness of the man. Twentieth-century criticism tends to see him as the tragic result of the civilization of the Renaissance.

Standard editions of Tasso's works are: *Le Rime*, ed. by A. Solerti (1898-1902); *La Gerusalemme liberata*, ed. by A. Solerti (1895-96), L. Caretti (1958); *Aminta*, ed. by B. T. Sozzi (1957); *La Gerusalemme Conquistata*, ed. by L. Bonfigli, 2 vol. (1934); *Dialoghi*, crit. ed. by E. Raimondi (1958); *Le Lettere* (1852-55) and *Prose diverse* (1875) ed. by C. Guasti; and *Appendice alle opere in prosa*, ed. by A. Solerti (1892). English editions include *Godfrey of Bulloigne, or the Recoverie of Hierusalem*, trans. by E. Fairfax (1600); *Jerusalem Delivered*, trans. by J. K. James, 2 vol. (1884); L. E. Lord, *A Translation of the Orpheus of A. Politian and the Aminta of T. Tasso* (1931).

Tasso (Bibliografia analitica: 1931-1945)," in *Aevum*, XX, pp. 14-72 (1946); and more recent, Tortoreto's annual contributions in the periodical *Studi Tassiani*. See also A. Solerti, *Vita di T. Tasso*, 3 vol. (1895); E. Donadoni, *T. Tasso: Saggio critico*, 2 vol. (1921); W. Boultong, *Tasso and his Times* (1907). (G. A.)

**TASTE:** see SMELL AND TASTE.

**TATA**, a Parsee priestly family, originally from the former Baroda state, India, that produced several distinguished merchants, industrialists and philanthropists. Founder of its greatness was JAMSETJI NASARWANJI TATA (1839-1904), educated at Elphinstone college, Bombay. Joining his father's trading firm in 1858 and aided by a powerful imagination, he entered on an outstanding career which contributed massively to India's industrial development. He organized cotton mills in Bombay and Nagpur; founded

the Tata Iron and Steel company, one of the largest integrated steelworks in the world; and planned the use of hydroelectric energy resulting in the formation, after his death, of the Tata Power companies, which supply electricity to Bombay city and the surrounding areas. He introduced sericulture into India; founded the Indian Institute of Science in Bangalore; applied the findings of science to the cultivation of cotton and other crops; built the Taj Mahal hotel; and established an endowment for the advanced professional and technical training of Indians abroad. A man of high social ideals, he was a pioneer in his attitude to labour, and devoted an overwhelming proportion of his firm's profits to practical philanthropy.

His sons, SIR DORABJI J. TATA (1859-1932) and SIR RATANJI TATA (1871-1918), inherited both his fortune and his traditions. Under their guidance the firm expanded into a group of associated companies, covering basic industries. Sir Ratanji founded a department of social science and administration at the London School of Economics, and financed certain social studies at the University of London. Sir Dorabji established a trust for international research into leukemia and endowed a hospital for cancer research in Bombay.

In 1932 on the death of Sir Dorabji, SIR NAOROJI SAKLATVALA, one of the founder's nephews, became chairman of the group. On his death in 1938, J. R. D. TATA (1904- ), whose father R. D. TATA was a cousin and partner of the founder, became chairman. By the late 1950s the group controlled the largest single aggregation of Indian industry, including among its interests not only textiles, steel and electric power, but also agricultural equipment, locomotives, diesel trucks, chemicals, cement, vegetable oils, soap and toilet products, insurance, radios and industrial investment. Eighty-five per cent of the capital of the parent company, Tata Sons Private Limited, was held by the various charitable trusts endowed by the family. (B. SH. S.)

**TATABÁNYA**, a town of northwest Hungary in Komárom megye (county), 35 mi. (56 km.) W of Budapest by road. Pop. (1960) 52,044. The town grew considerably after World War II and became the main settlement in the lignite basin between the Vértes Hills to the south and the Gerecse Mountains to the north. Much of Tatabánya's industry also derives from the bauxite resources of this part of Hungary, as the town marks the north-eastern extremity of the mining region. The manufacture of aluminium and the chemical industries are well established, and there are two large thermoelectric stations. Tatabánya ranks with Székesfehérvár as one of the most vigorous urban centres of northwest Hungary. (H. G. S.)

**TATAR** (TARTAR), a member of a Turkic-speaking people whose main seat is in the U.S.S.R. along the central course of the Volga River and its tributary the Kama, thence east to the Ural Mountains. They are also settled widely in eastern and south-eastern European U.S.S.R. and in southern Siberia. They numbered about 5,000,000 in the 1960s (comprising the largest ethnic minority in the Russian Soviet Federated Socialist Republic). Linguistically, they belong to the northwestern or Kipchak (q.v.) branch of the Turkic languages (q.v.). The ancient name Tatar has been attributed to many groups with little or no relationship to the people identified here. The name was sometimes given to single tribes or to all nomads of the Asian steppes and deserts, including Mongols and Turks generally (early Chinese and Russian sources). The term likewise was applied to peoples and states of the Mongol Empire (13th-14th centuries A.D.): Crimean Tatars, Siberian Tatars, Kazan Tatars, Kasimov Tatars.

Among elements entering into the composition of the Tatars of the Volga were Turkic nomads of the south Russian steppe (Kipchak and others) dating from the first millennium A.D. Ancient Bulgaria (not to be confused with modern Bulgaria) covered in part the territory of modern Tataria (see BULGARIA [on the Volga]). Other elements were added by the establishment of the Mongol Empire in Russia and by the defeat of Kazan (q.v.) by Ivan the Terrible in 1552. Neighbouring peoples were absorbed, including some Chuvash and Mordvin (q.v.), as late as the 19th century.

A distinct group on the Oka River near Kasimov, their former

capital, are the Kasimov Tatars (reported since the 15th century), who still preserve their identity even when they live among the Volga Tatars. Mishar Tatars also live in the territory; grouped with them are the Meshcheryak Tatars under the cultural influence of the Bashkir (*q.v.*), although preserving Tatar speech; Teptyar Tatars also have settled among the Bashkir. Karagash are a small Tatar group near the city of Astrakhan (*q.v.*). Kryashen Tatars are a large Christian group who live among the Muslim majority of Tatars; the Nagaybak Tatars near Chelyabinsk are a much smaller Christian group descended from the Kryashen.

From the 9th to 15th centuries Tatar economy was based on mixed farming and herding, nomadic peoples being absorbed during the Middle Ages. Having long been sedentary, they continue to farm and to breed livestock and have an ancient tradition of craftsmanship in wood, ceramics, leather, cloth, and metal. The Tatars have long been famous as traders; during the 18th and 19th centuries they earned a favoured position within the expanding Russian Empire as commercial and political agents, teachers, and administrators of newly won Central Asian territories.

As a medieval power, the Tatars had a complex social organization; the nobility preserved its civil and military leadership into Russian times, following the conquest of Kazan; distinct classes of commoners were merchants and tillers of the soil. At the head of government stood the khan of the Tatar state, part of whose family joined the Russian nobility by direct agreement in the 16th century. This stratification continued until the Russian Revolution.

The Tatars were converted to Islam in the 14th century and, as Sunnites, were instrumental in bringing the faith to Turkistan. Still surviving, however, are such pre-Islamic practices as folk beliefs in spirits of the forest, of the water, and of the household.

**TATAR AUTONOMOUS SOVIET SOCIALIST REPUBLIC** (TATARSKAYA AVTONOMNAYA SOVETSKAYA SOTSIALISTICHESKAYA RESPUBLIKA), in the Russian Soviet Federated Socialist Republic, U.S.S.R., lies in the middle Volga Basin around the confluence of the Volga and Kama rivers. It was formed in 1920 and covers an area of 26,255 sq.mi. (67,600 sq.km.). The Volga flows north-south across the western end of the republic, while the Kama, its largest tributary, forms a roughly east-west axis through the greater part. Within the republic the Kama is joined by its two major tributaries, the Vyatka and the Belaya. Generally, the relief is that of a low, rolling plain. The area west of the Volga is higher and rises to 771 ft. (235 m.), representing the extreme northern end of the Volga Uplands, which form a high right bank of the river. The land also rises in the east of the republic toward the Urals Foreland. The southeast is occupied by the Bugul'ma-Belebey Upland, which reaches a height of 1,220 ft. (371 m.). The climate is markedly continental, with prolonged, severe winters and hot summers. At Kazan the January average temperature is  $-13.8^{\circ}\text{C}$  ( $7^{\circ}\text{F}$ ) and the July average  $20^{\circ}\text{C}$  ( $68^{\circ}\text{F}$ ). Annual rainfall is about 15–16 in. (380–405 mm.), with a summer maximum. Snow cover may be up to 24 in. thick.

The greater part of the republic lies in the forest-steppe zone on degraded or podzolized chernozems (black earths). The northwestern part is in the area of broad-leaved forest, chiefly oak and lime on gray forest-earth soils, but centuries of clearing have greatly reduced the forest area. Regions of poor, sandy soil are typically under pinewood. Along the rivers are broad, floodplain meadows, although those on the Volga and lower Kama have disappeared under the waters of the Kuybyshev (Kuibyshev) Reservoir, which extends up the Volga through the whole republic and up the Kama to Bondyuzhskiy. Altogether more than 1,100 sq.mi. (2,850 sq.km.) of the republic have been flooded by the reservoir.

The Tatars are a Turkic people (see TATAR; TURKIC PEOPLES) and the descendants of the Mongols of the Golden Horde, who established themselves in this area in the mid-13th century, largely replacing or absorbing the previous Bulgar population. As the

Golden Horde declined in power in the 15th century, it split into separate groups, of which the Kazan khanate was the most northerly. The khanate was for long engaged with Muscovy in a struggle that was finally resolved in 1552 when Ivan IV, the Terrible, besieged and captured Kazan. Several revolts followed, but they were severely crushed. Attempts to convert the Tatars forcibly to Orthodoxy led to their participation in the Pugachev revolt of 1773–74. After the Russian conquest of Kazan, colonization began, and fortified lines were established in the Trans-Kama to protect the newly won lands. (See also KAZAN.)

The population in 1959 was 2,850,417, of which about 47% was Tatar, the remainder being Russian, with small numbers of Chuvash, Udmurt, Mordva, and Bashkir. (The Tatars in 1959 numbered 4,967,700 in the U.S.S.R. as a whole.) Of the Tatar Republic, 42% of the population was urban. There are 14 towns and 22 urban settlements. The largest of the towns are Kazan (646,806), the capital, Bugul'ma (60,980), Zelenodol'sk (60,472), and Al'met'yevsk (48,611).

An important factor facilitating the growth of industry in the Tatar A.S.S.R. since the Revolution is its location between the core region of the U.S.S.R. around Moscow, the Urals industrial area, and the Second Baku oil field, while the Volga and Kama rivers, with the navigable Vyatka and Belaya, form major routeways linking all three areas. The Bugul'ma-Belebey Upland in the southeast forms part of the Second Baku oil field. The first well was drilled in 1943, and subsequent development was very rapid. Al'met'yevsk, one of the main oil towns, was a village in 1939. Other centres are Bugul'ma, Leninogorsk, Aznakayevo, and Bavl'y. Pipelines run from Al'met'yevsk west to Gorki and east to Sverdlovsk. Together with petroleum, natural gas is obtained, the chief centre being at Minnibayevo, which has a gas pipeline to Kazan. The petroleum, with the salts of the upper Kama, has encouraged the growth of the chemical industry, chiefly at Kazan and Bondyuzhskiy. Engineering works are concentrated largely in the towns along the Volga and Kama, notably at Kazan, Zelenodol'sk, and Chistopol'. Timber working is widespread and includes the production of crates and boxes, prefabricated houses, furniture, and veneer. Paper and pulp are made at Mamadysh and at a group of neighbouring towns on the Kama. Also widespread is the processing of leather and furs, particularly for making shoes and felt boots. The manufacture of soap and other fat products is important in Kazan. Some linen and cotton cloth is made.

Agriculture is also important, and 57% of the republic is arable. Dredge corn (rye and oats together) is widely grown, but spring wheat, maize (corn), millet, and buckwheat are also significant. A large area is sown with legumes, especially peas and lentils. Potatoes, sugar beet, hemp, and sunflowers are valuable industrial crops, while tobacco is grown in the Volga right-bank area. Around Kazan market gardening is developed, and the Volga villages are noted for their apple orchards. Cattle, especially dairy cows, are kept in considerable numbers, as are sheep and goats. Before the Revolution the Tatars rarely kept pigs, but the number of pigs is steadily increasing.

There is heavy freight traffic along the rivers, with rafted timber forming the largest commodity (around 2,500,000 tons a year). Regular passenger services also connect the river ports of the republic to Moscow and all parts of the Volga Basin. The republic is less well served internally by railways, although two main lines between Moscow and the Urals cross the northwest and southeast corners. Work was in progress in the 1960s to link these main lines by a meridional railway from Agryz to Bugul'ma. Another line runs north-south through the Volga right-bank area.

(R. A. F.)

**TATE, (JOHN ORLEY) ALLEN** (1899– ), U.S. poet and critic known as the author of "Ode to the Confederate Dead" and other intellectual poetry, but whose greatest influence was in criticism, was born in Clarke county, Ky., on Nov. 19, 1899. He was graduated in 1922 from Vanderbilt university, Nashville, Tenn., where he was a pupil of John Crowe Ransom and a member of the group of poets known as "Fugitives" and of the social commentators, "Agrarians" (see their *I'll Take My Stand*, 1930, which criticized the current faith in industrial progress).

Tate taught English at Southwestern college, Memphis, Tenn.; North Carolina College for Women, Greensboro; Princeton university; and the University of Minnesota, Minneapolis. His one novel, *The Fathers* (1938), enjoyed a success of esteem. Most of his poems are collected in *Poems, 1922-47*, and his volumes of critical essays include *Reactionary Essays on Poetry and Ideas* (1936), *Reason in Madness* (1941), *On the Limits of Poetry* (1948) and *The Forlorn Demon* (1953). Tate's "Miss Emily and the Bibliographers" challenged the domination in literary studies of the historical school of scholarship; his "Emily Dickinson" adumbrated that poet's fame. The view of the nature of poetry set forth in such essays as "Literature as Knowledge" and "Tension in Poetry" became a commonplace of modern analytic criticism.

See John M. Bradbury, *The Fugitives* (1958). (R. St.)

**TATE, SIR HENRY** (1ST BART.) (1819-1899), English sugar refiner, philanthropist and founder of the Tate gallery in London, was born at Chorley, Lancashire, on March 11, 1819, the son of a Unitarian minister. Starting life as a grocer's assistant in Liverpool, he eventually became a prosperous sugar refiner. By 1878 he extended his business to London where he built a second sugar refinery, with outstanding success. Among numerous benefactions he built, equipped and endowed the Hahnemann hospital, Liverpool, provided a library for Liverpool University college and another for Manchester college, Oxford, and gave three public libraries to the London districts of Brixton, Streatham and South Lambeth. Tate's offer to the nation of his private collection of 19th-century pictures, together with the money for a building, was accepted in 1892, and the National Gallery of British Art (known as the Tate gallery) was opened at Millbank, London, on July 21, 1897. Two years later, by his further generosity, the accommodation was almost doubled.

Tate became a trustee of the National gallery in 1897 and was made a baronet in the following year. He died at Streatham on Dec. 5, 1899.

See R. H. Blackburn, *Sir Henry Tate* (1940).

**TATE, NAHUM** (1652-1715), English poet laureate and playwright, adapter of other men's plays, collaborator with Nicholas Brady (*q.v.*) in the famous *New Version of the Psalms* (1696). He was born in Dublin, Ire., graduated from Trinity college there and moved to London. Tate wrote some plays of his own but he is best known for his adaptation of the Elizabethans. His version of Shakespeare's *King Lear*, to which he gave a happy ending in which Cordelia married Edgar, held the stage well into the 19th century.

Tate also wrote the libretto for Purcell's *Dido and Aeneas* (*c.* 1689). Some of his hymns found a lasting place in Protestant worship—"While shepherds watched"; "Through all the changing scenes of life"; and "As pants the hart for cooling streams."

Tate was commissioned by Dryden to write the second part of *Absalom and Achitophel* (1682), although Dryden added the finishing touches (probably including the portraits of Elkanah Settle and Thomas Shadwell) himself.

The best of Tate's own poems is *Panacea, a Poem on Tea* (1700). He succeeded Shadwell as poet laureate in 1692 and died in London on July 30, 1715. The belief that Tate lived until 1716 long caused it to be thought that he was superseded as poet laureate during his lifetime.

**TATIAN** (TATIANUS) (2nd century A.D.), Christian apologist, missionary and heretic, and editor of the *Diatessaron* (*i.e.*, the four Gospels in a continuous narrative). He was born in Mesopotamia of Syrian parentage and educated in Greek learning, in which he became proficient. He was initiated into the mysteries, though into which is not known, but after this became acquainted with the Old Testament and was converted to Christianity. Tatian then went to Rome, where he was a hearer of Justin Martyr.

After the death of Justin, Tatian became a heretic. Among his pupils were Rhodon, and, perhaps, Apelles and Clement of Alexandria. He made a missionary journey to the east and worked in Cilicia and Pisidia, using Antioch in Syria as the centre of his efforts.

The heresy that Tatian either founded or adopted was the Gnostic heresy of the Encratites. Their main doctrines were the

evil nature of matter, an absolute forbidding of marriage, abstinence from wine and perhaps from meat. It would also seem that Tatian believed in the existence of aeons, one of whom was the Demiurge of the world. He denied the salvation of Adam. It is also stated that in his celebration of the mysteries (*i.e.*, the Eucharist) he used only water.

According to Eusebius, Tatian wrote many books; of these the names of the following survived: *On Animals*, *On Demons*, *Address to the Greeks*, *Book of Problems* (an attempt to deal with contradictions found in the Bible), *Against Those Who Have Discussed Divine Things*, *On Perfection According to the Saviour*, the *Diatessaron*, and a recension of the Pauline epistles. Of these books only two—the *Diatessaron* and the *Address to the Greeks*—are extant. The *Address to the Greeks* belongs to Tatian's Catholic period. He has the double purpose in view of exposing the weakness of the pagan view of the universe and of commending the Christian explanation. The omissions in the *Address* are even more remarkable than its statements. There is at the most not more than an allusion to Christ, who is never mentioned by name, and though there are frequent allusions to the regaining of life, which is accomplished by union with the Logos, there is no reference to the doctrines of the incarnation or of the atonement.

Editions of the *Address to the Greeks* are found in O. von Gebhardt and A. Harnack, *Texte und Untersuchungen zur Geschichte der altchristlichen Literatur*, vol. iv (1888), and E. J. Goodspeed, *Die ältesten Apologeten*, pp. 266-305 (1914); an English translation by B. P. Pratten was published in the "Ante-Nicene Christian Library," vol. iii, pp. 3-48 (1867).

See also *DIATESSARON*.

(B. M. M.)

**TATRA MOUNTAINS** (HIGH TATRA), the highest range of the central Carpathians, rise steeply from a high plateau (2,600 ft. [793 m.]) along the Polish-Czech border, varying in width toward Czechoslovakia from 9 to 15 mi. (14-24 km.) and running from west to east about 40 mi. (64 km.). With the frontier running along the summit, the whole area forms the Tatra National Parks ("Tanap"), both Polish and Czech. The highest peaks include Gerlachovka (8,711 ft. [2,655 m.]); Lomnica Peak (8,635 ft. [2,632 m.]); and the Kriváň (8,182 ft. [2,494 m.]), depicted in Czechoslovakia's national emblem. Without glaciers or permanent snowfields, the High Tatras otherwise resemble the Alps. With numerous small lakes, the mountains have many summer resorts and centres for winter sports.

South of the Vah River Valley runs a lower parallel range, the Low Tatra, reaching its maximum heights in the peaks of Dumbier (6,703 ft. [2,043 m.]) and Kráľova Hôľa (6,391 ft. [1,948 m.]).

**TATTOOING** is the introduction of pigment through ruptures in the skin. Sometimes the term is loosely applied also to scarification (see *MUTILATIONS AND DEFORMATIONS*; *BRANDING*). Tattooing proper has a nearly world-wide distribution, except that it is rare among populations with the darkest skin colour, and was absent from most of China (at least in recent centuries). Among various peoples tattooed designs are thought to provide magical protection against sickness or misfortune, or serve to identify the wearer's rank, status or membership in a group. Decoration is perhaps the commonest motive for tattooing.

Tattooing occurs on Egyptian mummies dating from about 2000 B.C., and is mentioned by classical authors for the Thracians, Greeks, Gauls, ancient Germans and ancient Britons; the Romans tattooed criminals and slaves. After the advent of Christianity tattooing was forbidden in Europe, but persisted in the near east and in other parts of the world.

In the Americas many Indian tribes customarily tattooed the body or the face, or both. The usual technique was simple pricking, but some California tribes introduced colour into scratches, and many tribes of the arctic and subarctic, most Eskimos and some peoples of eastern Siberia, made needle punctures through which a thread coated with pigment (usually soot) was drawn

underneath the skin. In Polynesia, Micronesia and parts of Malaysia pigment was pricked into the skin by tapping on an implement shaped like a miniature rake. In moko, a type of Maori (q.v.) tattooing, shallow coloured grooves in complex curvilinear designs were produced on the face by striking a miniature bone adze into the skin. In Japan needles set in a wooden handle are used to tattoo very elaborate multicoloured designs often covering much of the body. Burmese tattooing is done with a brass penlike implement with a slit point and a weight on the upper end. Sometimes pigment is rubbed into knife slashes (e.g., in Tunisia, among the Ainu of Japan, Ibo of Nigeria and Chontal Indians of Mexico); or the skin is punctured with thorns (Pima Indians of Arizona and Senoi of Malaya) or other simple needlelike implements.

Tattooing was rediscovered by Europeans when the age of exploration brought them into contact with American Indians and Polynesians. The word tattoo itself was introduced into English and other European languages from Tahiti, where it was first recorded by James Cook's expedition in 1769. Tattooed Indians and Polynesians, and later Europeans tattooed abroad, attracted much interest at exhibits, fairs and circuses in Europe and the U.S. during the 18th and 19th centuries. Stimulated by Polynesian and Japanese examples, tattooing "parlours" where specialized "professors" applied designs on Euroamerican sailors sprang up in port cities all over the world. The first electric tattooing implement was patented in the U.S. in 1891. The U.S. became a centre of influence in tattoo designs, especially with the spread of U.S. tattooers' pattern sheets. The nautical, military, patriotic, romantic and religious motifs are now similar in style and subject matter throughout the world; characteristic national styles of the early 20th century have disappeared.

In the 19th century released U.S. convicts and British army deserters were identified by tattoos, and later the inmates of Siberian prisons and Nazi concentration camps were similarly marked. Tattooing has long been especially characteristic of European and U.S. sailors. Before World War I tattooed symbols of other occupations were very common in continental Europe and sometimes occurred in England. Members of criminal gangs still frequently identify themselves with a simple tattooed device. During the late 19th century tattooing had a short vogue among both sexes in the English upper classes. Except for Euroamerican and Japanese types, and for special medical applications, tattooing is moribund or extinct in most parts of the world.

There are sometimes religious objections to the practice ("You shall not make any cuttings in your flesh on account of the dead or tattoo any marks upon you . . ." Lev. xix, 28). Tattooing has been implicated in such disorders as skin cancer, and in 1961 the practice was sharply restricted by the New York city government because of the role of contaminated tattooing equipment in spreading hepatitis (see GALL BLADDER, BILIARY TRACT AND LIVER, DISEASES OF).

**TATUM, EDWARD LAWRIE** (1909— ), U.S. biochemist, who shared the 1958 Nobel Prize for Medicine or Physiology with George W. Beadle and Joshua Lederberg (q.v.) for research in genetics, was born in Boulder, Colo., on Dec. 14, 1909. He was educated at the University of Chicago and the University of Wisconsin (A.B., 1931; Ph.D., 1934). His doctoral thesis dealt with the nutrition and biochemistry of bacteria. Following a year of postdoctoral study in The Netherlands, Tatum went to Stanford University where he collaborated with Beadle on research into the biochemical aspects of heredity. This work was carried out on the common fruit fly, *Drosophila*, and especially the red bread mold, *Neurospora*, but the principles derived from it are of wide application in biology. One application was to the study of the genetics of bacteria—a field of research opened to modern techniques by Tatum and Lederberg at Yale University in 1946. In 1957 Tatum went to the Rockefeller Institute as a member and professor. (N. H. H.)

**TAULER, JOHANN** (c. 1300–1361), German Dominican, together with Meister Eckhart and Heinrich Suso (q.v.) one of the Rhineland mystics, was born in Strasbourg. Educated at the Dominican convent at Strasbourg and the *studium generale* at Cologne, he later became a lector at Strasbourg. During a period of exile, Tauler preached and lectured in Basel, returning again in 1347–48 to Strasbourg, where he died on June 16, 1361. He was greatly influenced by Eckhart, though his teaching, based on Thomas Aquinas, stresses practical rather than speculative mystical theology. References to the "Friends of God" (*Gottesfreunde*) appear in his sermons (written in Middle High German and valued highly by Martin Luther), alluding to a circle of like-minded devout Rhinelanders much influenced by Tauler, Eckhart, and Suso.

**BIBLIOGRAPHY.**—Sermons ed. by F. Vetter (1910), Eng. trans. by Walter Elliott (1910). See also P. Strauch, "Zu Taulers Predigten," *Beiträge zur Geschichte der deutschen Sprache und Literatur*, 44:1–26 (1920); J. M. Clark, *The Great German Mystics* (1949).

**TAUNTON**, a market town and municipal borough (1877) and the county town of Somerset, Eng., in the Taunton parliamentary division, 48 mi. (77 km.) SW of Bath by road. Pop. (1961) 35,192. Area 3.8 sq.mi. (10 sq.km.). It lies on the River Tone in the Vale of Taunton Deane, sheltered on three sides by the Quantock, Blackdown, and Brendon hills. The town was founded by the Saxon king Ine, who built the first castle there about A.D. 710. The bishops of Winchester, who owned the manor, obtained their first charter from Edward the Elder in 904. Bishop Giffard of Winchester built the second castle early in the 12th century and founded a priory of Augustinian canons in 1127. During the English Civil War the castle was thrice besieged by royalists, before Sir Thomas Fairfax relieved the town in 1645, and at the Restoration Charles II deprived Taunton of its charter of incorporation. The castle was dismantled, apart from its gateway and the great hall where Judge Jeffrey's "Bloody Assize" took place after the failure of the Monmouth rebellion at the Battle of Sedgemoor in 1685.

Taunton, in the diocese of Bath and Wells, is the seat of a suffragan bishopric. The churches of St. Mary Magdalene and St. James are Perpendicular in style. Huish's Grammar School shares in the endowment of Robert Huish, who died in 1615; Taunton, King's College, Queen's College, and Wellington are local public schools; in the town are a technical college and the Somerset College of Art. In Taunton is the Somerset County Cricket Club ground. There are hunting and fishing in the district.

The Saturday market, dating from before the Conquest, has become one of the largest livestock and produce markets in the southwest. Shirts and collars and agricultural machinery are manufactured.

**TAUNTON**, a city of Massachusetts, U.S., and seat of Bristol County, is 35 mi. (56 km.) S of Boston at the head of navigation on the Taunton River, 14 mi. (23 km.) above Fall River. The centre of Taunton, the "Green," is about one mile from the Weir, the port of the city. Taunton was settled after purchase of land from the Indians and in 1639 became a town with representatives in the general court of Plymouth colony. The name was derived from the English home of many of the settlers. In the 18th century six towns were detached from the original grant.

Taunton was a base of operations during King Philip's War (1675–76). In 1687 a town meeting declined to meet a tax levy by Sir Edmund Andros "without their own assent in an assembly." A Liberty pole with a flag inscribed "Liberty and Union" was raised on the "Green" in 1774 to express opposition to the Boston Port Bill. During Shays's Rebellion in 1786–87 the courthouse was twice besieged by insurgents who were dispersed each time by a judge, Gen. David Cobb.

Ironworks, established in 1656, were operated successfully until 1876; iron bars were sometimes used as a medium of exchange. Brickmaking and shipbuilding were other early industries. Silverware production, begun in 1824, remains important. Modern industries also include jewelry, plastics, and electronics.

The nearby Dighton rock has inscriptions long attributed to the Norse, but believed now to be the work of Indians or of a Portuguese explorer. Taunton became a city in 1864. For com-

parative population figures *see* table in MASSACHUSETTS: *Population*. (CA. M. C.)

**TAUNUS**, a wooded highland of West Germany, extending over parts of the *Länder* (states) of Hesse and Rhineland-Palatinate, Federal Republic of Germany. It lies to the east of the Rhine with the Main on the south and the Lahn on the north and is about 50 mi. (80 km.) long. Its southern edge stands 5–10 mi. (8–16 km.) back from the Main but slopes steeply to the Rhine, and from Bingen downstream forms precipitous crags. The average elevation is 1,500 ft. (460 m.), with a higher ridge above the Rheingau (the slopes to the Rhine between Biebrich and Bingen). The highest points occur in the east, where the Grosser Feldberg (2,887 ft.; 880 m.), Kleiner Feldberg (2,710 ft.; 826 m.), and Altkönig (2,618 ft.; 798 m.) dominate the Wetterau and the valley of the Main. The geological core of the system consists of (P)Archean argillaceous schists, capped by quartzite (Devonian) and broken through in places by basalt. On the northern side, which sinks on the whole gently toward the Lahn, the higher graywacke formation (Devonian) is considerably developed. The hills are generally well wooded with beech, with some pine plantations; large areas of forest were cleared for cultivation in the Middle Ages. The lower slopes are, where possible, planted with vineyards, orchards, and chestnut and almond groves. The Rheingaugebirge, in the Rhine gorge, has vineyards that yield famous wines. The Taunus is also famous for its mineral springs and health resorts; *e.g.*, Wiesbaden, Königstein, Bad Homburg.

Among numerous ancient ruins are the castle of Falkenstein; the fortress of Königstein; a Cistercian abbey at Eberbach; and two concentric lines of pre-Roman fortifications at Altkönig. The chief historical monument, however, is the Saalburg, a Roman fort serving as a centre of communications along the *limes* (*q.v.*), or fortified frontier line drawn from Rhine to Main by Domitian.

At Niederwald above Rüdesheim stands the gigantic "Germania" statue commemorating the war of 1870–71. The steep crags of the western end of the Taunus, where they abut upon the Rhine, are rich in the romantic associations of the great river. There are the rock of the siren Lorelei, the old castles of Stahleck and Pfalz, and the quaint medieval towns of Lorch, Kaub, and St. Goarshausen.

(R. E. DI.)

**TAURI**, the earliest known inhabitants of the mountainous south coast of the Crimea, called after them in ancient times the Tauric Chersonese. Nothing is certain as to their affinities. They were not Scythians and are not likely to have been Celts. They were famous in the ancient world for their virgin goddess, identified by the Greeks with Artemis Tauropolos or with Iphigenia (*q.v.*). The Tauric custom of sacrificing shipwrecked strangers to the goddess was the ground of the story of Iphigenia and Orestes among the Tauri, which is the subject of plays by Euripides (*Iphigenia in Tauris*) and Goethe (*Iphigenie auf Tauris*). The Tauri were given to piracy on the Black Sea. Toward the end of the 2nd century B.C. they were dependent allies of the Scythian king Scilurus, who from their harbour of Symbolon (Balaklava) harassed Chersonese (*see* CHERSONESE, TAURIC). Their later history is unknown.

(E. H. M.; X.)

**TAURUS** ("the Bull"), in astronomy, the second sign of the zodiac. It is a constellation of very great antiquity, the Pleiades and Hyades (*qq.v.*), two of its constituent star clusters, being possibly referred to in the Old Testament; Aldebaran, its brightest star, is mentioned by Hesiod and Homer. The Greeks fabled this constellation to be the bull which bore Europa across the seas to Crete and was afterward raised to the heavens by Jupiter. Aldebaran is the principal object in the Hyades. Many of the Hyades (but not including Aldebaran) form an associated group of stars with a common motion. The measurement of the motions of these stars permits an accurate determination of their distance; these measurements show that they are situated at approximately 130 light years from the sun.

Aldebaran itself is a reddish giant star, located at a distance of about 80 light years from the sun. The constellation contains the "Crab nebula," a gaseous mass which has been shown fairly conclusively to have originated in the outburst of the new star, or nova, of A.D. 1054. Photographs indicate that the nebula is ex-

panding in size from year to year. The structure of the Milky Way in Taurus is complex, with dark, almost starless lanes and bright nebulosity.

**TAUSEN, HANS** (1494–1561), the protagonist of the Danish Reformation, called "the Danish Luther," was born at Birkende on the island of Fyn. He joined the order of the Knights Hospitalers at Antvorskov, near Slagelse, and after studying and teaching at Rostock (1516–21) and Copenhagen (1521–22), he visited the University of Louvain (1522), where he made the acquaintance of the Flemish humanists. He became a good linguist, understanding both Greek and Hebrew. In 1523 he went to Wittenberg, where he studied for a year and a half before being recalled to Antvorskov. Most of the Danish reformers were influenced by the Reformation in south Germany and Switzerland, but Tausen was more directly inspired by Luther himself, and the victory of the Lutheran type of Reformation in Denmark was largely due to him. In consequence of his doctrines he may have been imprisoned at Antvorskov; in 1525 he was confined in his order's priory at Viborg in Jutland, where he preached from his prison to the people assembled outside, till his prior lent him the pulpit of the priory church.

After revolts against the youthful bishop Jørgen Friis on the part of young burghers who had studied in Germany, Tausen left the Hospitalers in order to preach in the town under the burghers' protection. They prevented his arrest by the bishop, and in October 1526 he was made an official Lutheran chaplain by King Frederick I. Tausen found a fellow worker in Jørgen Jensen Sadolin, whose sister he married. He probably was the first Danish priest to marry; he also was the first to use Danish instead of Latin in the church services, and the manuals he published were of great importance not only for the Lutheran congregation in Viborg but also for creating a Reformed liturgy in Denmark.

In 1529 Tausen was transferred to Copenhagen, and there he continued his work with great success. But after the death of the king he was accused of blasphemy by Bishop Joachim Rønnow (1533) and condemned to expulsion from the dioceses of Sjælland and Skane. The people then rose in arms against the bishop, who might have been murdered but for Tausen's intervention. Rønnow then permitted him to preach everywhere in the diocese on condition that he moderate his tone. In 1535 he published a translation of the Pentateuch from the Hebrew. On the final triumph of the Reformation (1536) Tausen was made a lecturer of Hebrew in the reorganized University of Copenhagen (1537), and in 1542 he became bishop of Ribe, an office that gave him many difficulties, especially with the nobility of Jutland. He died at Ribe on Nov. 11, 1561.

(P. G. L.)

**TAUTOLOGY**, from a Greek word meaning "saying the same thing," is a word used technically in logic in a sense somewhat different from that in which it is used, pejoratively, in grammar. In the latter, a tautology is a needless repetition of a single idea in several words, as if more than one idea were being expressed (*see* FIGURES OF SPEECH).

In logic, the notion of a tautology in the propositional calculus is due to C. S. Peirce (1885). For this notion, and for the symbols used in this article, *see* LOGIC: *The Propositional Calculus*. The name tautology, however, was introduced in 1921 by Ludwig Wittgenstein, whose philosophical use of the notion, outlined in the article LOGICAL POSITIVISM, requires its extension from the propositional calculus to the full theory of types, including the functional calculi of first and higher orders. This extended notion, which was explained somewhat cryptically by Wittgenstein, and more satisfactorily by F. P. Ramsey in 1926, is, in fact, a less precise forerunner of what is now more usually called "validity" (*see* LOGIC: *The Metatheory of the Pure Functional Calculus of First Order*). Later logical positivists, especially Rudolf Carnap, amended Wittgenstein's doctrine in the light of the distinction that there is an effective test of tautology in the propositional calculus but no such test of validity even in first-order functional calculus.

As an example of a tautology in the extended sense of Wittgenstein-Ramsey, consider the formula  $p \supset F(x) \supset p \supset (x) F(x)$

which is a theorem (in fact an axiom) of the pure functional calculus of first order. Suppose that there is available a list, possibly infinite, of names for all the individuals, say:  $i_1, i_2, i_3, \dots$ . Then replace the two universal quantifiers that occur in the formula, each by a corresponding conjunction, so that we have:

$$[p \supset F(i_1)] [p \supset F(i_2)] [p \supset F(i_3)] \dots \supset p \supset F(i_1) F(i_2) F(i_3) \dots$$

This last may not be properly a formula, that is to say, it may be infinite in length, so that it is impossible actually to write it out. Nevertheless, we may abstractly consider such quasi-formulas; and in the same abstract way we may consider truth-table computations (or better, quasi-computations) applied to them, which may be infinite in width and length but are otherwise just like the finite truth-table computations that were explained in the article LOGIC in connection with propositional calculus. Moreover, in the case of the particular quasi-formula in question, it is clear that it is a tautology in the sense that, for every assignment of truth-values to its elementary parts  $p, F(i_1), F(i_2), \dots$ , the truth-table computation assigns to the whole quasi-formula the value truth. The analogy to the notion of tautology in the propositional calculus fails in only one respect: because the truth-table computation may be infinite, effectiveness is lost. Wittgenstein and Ramsey characterized logic by the property that its theorems are tautologies in this extended sense. (A.O.C.)

**TAUTOMERISM**, in chemistry, is one basis upon which pure chemical compounds can behave as if they possess two or more distinct structures. In those instances in which the structures in question correspond to identical, or nearly identical, relative positions in space of all constituent atoms (see STEREOCHEMISTRY), the phenomenon is at present considered to find its explanation in the theory of resonance (see RESONANCE). In those other instances, however, in which the structures in question correspond to widely different relative positions of at least one atom, the phenomenon is explained in a different manner, and the term "tautomerism" has been coined for its description. The present article is concerned only with tautomerism in this sense, and no further mention of resonance will be made here. (For a description of a widely useful compound with tautomeric characteristics, see ACETOACETIC ESTER.)

It is commonly believed that any compound which exhibits tautomerism is an equilibrium mixture of two or more substances, and that these substances have the structures indicated by the behaviour of the mixture. A tautomeric mixture then must exhibit the reactions to be expected of all structures involved since all the corresponding substances are actually present. On this view, the reason that a tautomeric mixture appears to be a single pure substance is that its various components (or tautomerides, as they are often called) are capable of rapid interconversion; consequently, they are separable from one another only with considerable difficulty, if at all. Moreover, it usually happens that only one of the tautomerides is present to an appreciable extent in the equilibrium mixture.

An alternative explanation of tautomerism, which may be correct in some instances, is that all the molecules present have the same structure but are able to react in two or more different ways.

A typical example of tautomerism is provided by acetaldehyde, which behaves in most respects as if it has the stable, so-called keto structure I, but in other respects as if it has instead the unstable, so-called enol structure II. This compound has never been separated into its two assumed components,

I

II

and all attempts to prepare a substance (vinyl alcohol) with the structure II have led instead to ordinary acetaldehyde. The belief is universally held that acetaldehyde is essentially pure keto (I), and that only minute traces of the enol form (II) are present in equilibrium. For this reason, acetaldehyde is usually said to possess structure I. In methyl ethyl ketone, similarly, traces of the two enol forms IV and V are supposed to be present in addition to the stable keto form III.

III

IV

V

The above interpretation of tautomerism would seem highly arbitrary and not at all convincing if no tautomeric compounds were known which can actually be separated into the tautomerides. Fortunately, a few such compounds have been discovered. Of these, the one which has received the most careful study is doubtless acetoacetic ester (ethyl acetoacetate). On the one hand, this substance appears to be a typical ketone, as in VI, since it forms an oxime with hydroxylamine, a hydrazone with hydrazine, and a cyanohydrin with hydrogen cyanide (see ALDEHYDES AND KETONES).

VI

VII

Moreover, when treated with an excess of both sodium ethoxide and methyl iodide in alcoholic solution, it is transformed into a dimethyl derivative to which the structure VII can be definitely assigned. On the other hand, it appears to be a typical unsaturated alcohol, as in VIII, since it absorbs bromine very rapidly, gives a colour with ferric chloride, and has a pronounced acidic character. Moreover, when treated with diazomethane,

VIII

IX

$\text{CH}_2\text{N}_2$ , it is transformed into a methyl derivative to which the structure IX can be definitely assigned.

That this compound really is a mixture of two different substances with the structures under discussion was demonstrated in 1911 by L. Knorr, who found that the two components could be separated at  $-78^\circ \text{C}$ ., at which temperature their rate of interconversion is slow. At ordinary temperatures, the equilibrium mixture has been shown (K. H. Meyer, 1911) to consist of about 92.6% keto and 7.4% enol (in the pure liquid ester); these figures were obtained from a titration of the ester with bromine, with which the enol, but not the keto, form reacts rapidly.

A more complicated example of keto-enol tautomerism is presented by diacetylsuccinic ester, which has been obtained as the diketo form X, the keto-enol form XI, and the dienol form XII. (Actually, altogether five different forms of this ester are reported

X

XI

XII

to have been isolated; two of these are apparently stereoisomers of other forms.)

XIII

XIV

XV

XVI

In addition to the above keto-enol tautomerism, a number of

other types of tautomerism are also well known. For example, the amides of carboxylic acids (see AMIDES) exhibit the so-called lactam-lactim tautomerism. Thus, with acetamide, it is considered that the lactam form XIII predominates, but that the lactim form XIV may be present also in traces. Similarly, with a primary or secondary nitro compound (see NITRO COMPOUNDS), the nitro form, as in the structure XV of nitromethane, is considered to predominate greatly over the aci nitro form, as in XVI. A rather different type of tautomerism is illustrated by the fact that the same product results from the action of hydroxylamine upon benzoquinone as from the action of nitrous acid upon phenol.

From its first method of preparation, this substance should be the monoxime (see OXIMES) of benzoquinone with the structure XVII, whereas, from its second method of preparation, it should

be *p*-nitrosophenol with the structure XVIII. The oxime form XVII is considered to be the more stable, although with a few analogous compounds both forms are reported to have been obtained.

**Prototropy and Anionotropy.**—In the various types of tautomerism mentioned so far, the tautomeric structures differ in the position of a hydrogen atom (and also in the arrangement of the valence bonds). Most types of tautomerism, of which only a few have been described here, belong to this class; such tautomerism is sometimes designated by the special name of "prototropy" (from "proton," the nucleus of the hydrogen atom, plus the Greek *trepein*, to turn). A few examples are known, however, in which the structures differ in the position of some other atom or group of atoms (as well as in the arrangement of the valence bonds). Thus, the two unsaturated chlorides XIX and XX, and the corresponding alcohols XXI and XXII, are rather

XIX

XX

XXI

XXII

easily interconverted. The action of hydrogen chloride upon either alcohol gives a mixture of the two chlorides, and either chloride readily undergoes a partial spontaneous rearrangement into an equilibrium mixture of the two. Such tautomerism is sometimes referred to as "anionotropy" since the structures differ in the position of an atom or radical that is capable of forming a stable anion.

**Ring-Chain Tautomerism.**—A further important type of tautomerism can be illustrated with the example of 5-hydroxypentanal, which reacts with phenylhydrazine to give the phenylhydrazone XXIII, but with methyl alcoholic hydrogen chloride to give the cyclic product XXIV. In the first of these reactions,

the original compound appears to have the structure XXV, but in the second it appears to have the structure XXVI instead. This type of tautomerism occurs with those hydroxy aldehydes and ketones with which the cyclic form would have either a five-

XXV

or six-membered ring, and it is especially important in the sugar series.

See CARBOHYDRATES.

**TAVERNER, JOHN** (c. 1495–1545), English composer whose work represents the culmination of the tradition of elaborate polyphony practised in England in the first half of the 16th century. His name first appears in a visitation record as a clerk-fellow of the collegiate church of Tattershall in Lincolnshire in 1525. In October 1526 a letter from Bishop Longland of Lincoln to Cardinal Wolsey represents Taverner as being reluctant to give up his living at Tattershall "and the prospect of a good marriage which he would lose by removal"; nevertheless a month later he took up his duties as *informator* or master of the choir in the chapel of Wolsey's Cardinal College (later Christ Church), Oxford. In 1528 Taverner was accused of heresy and imprisoned on the charge that he had concealed heretical books. John Foxe records that "the Cardinal for his musick excused him, saying, that he was but a musitian, and so he escaped." In 1530 he left Oxford, at which time his musical career may be considered to have terminated.

He appears to have been an agent of Thomas Cromwell in the suppression of monastic establishments. He lived out his life in Boston, Lincolnshire, where in 1537 he was elected a member, and in 1541 a steward of the Guild of Corpus Christi. He died at Boston on Oct. 25, 1545.

Taverner's Latin church music, which includes six complete Masses, demonstrates a variety and skill, a range and a power that comes as the climax of pre-Reformation English music. In the field of instrumental music, an adaptation of the section of the *Benedictus* of his Mass *Gloria tibi Trinitas* associated with the words *In nomine Domine* became the prototype of a large number of instrumental compositions known as *In nomine* or *Gloria tibi Trinitas* during the succeeding century and a half.

See *Tudor Church Music*, vols. i and iii (1923, 1924); H. B. Collins, "John Taverner's Masses," in *Music and Letters*, vol. v (1924). (Jo. D. B.)

**TAVISTOCK**, a market town and agricultural centre in the Tavistock parliamentary division of Devon, Eng., 15 mi. (24 km) N of Plymouth by road. Pop. of urban district (1961) 6,988. It lies in a deep valley below the western edge of Dartmoor where one of the main routes into Cornwall crosses the Tavy. It was once the centre of an important mining district for tin and copper and is one of the four stannary towns of Devon. Its medieval importance owes much to the magnificent Benedictine abbey of St. Mary and St. Rumon founded in 961 by Orgar, earl of Devon. After destruction by the Danes in 997 it was rebuilt, and among its famous abbots were Lyfing, friend of Canute, and Aldred, who crowned Harold II and William and died archbishop of York. At the time of the Conquest it ranked as the wealthiest house in Devon, including the hundred and manor of Tavistock among its possessions. Most of the abbey was demolished at the dissolution and the lands given to the dukes of Bedford; in 1912 the council acquired some of this land from the duke. Remains of the abbey include the gateway which now houses the Tavistock library. The church of St. Eustachius dates from 1318 and possesses a lofty tower supported on four open arches; the "cloth-workers' aisle" (1445) witnesses to the importance of the town as a wool centre. Kelly College, near the town, founded by Adm. B. M. Kelly and opened in 1877, is now a public school for boys.

Henry I granted the abbots a market in 1105 and the famous Tavistock goosey fair in 1106. This takes place annually on the second Wednesday in October. In 1513 the abbots were granted a seat in the house of lords. Tavistock is a borough by prescription and returned two members to parliament from 1295 until 1867; in 1885 it was disfranchised.

**TAVOY**, a town and district in the Tenasserim division of Burma. The town lies on the left bank of the river of the same name, 30 mi. (48 km.) from the Andaman Sea and 150 mi. (241 km.) S of Moulmein. Pop. (1953) 40,312. A considerable coasting trade was developed with other ports of Burma and with Singapore, which received the bulk of the tin ore for which the district became important.

**TAVOY DISTRICT** has an area of 5,404 sq.mi. (14,000 sq.km.) and a population (1962 est.) of 297,871. It lies between lower Thailand and the Andaman Sea of the Bay of Bengal, enclosed by mountains on three sides, viz., the main chain of the Bilaukaung on the east, rising in places to 5,000 ft. (1,500 m.), which, with its densely wooded spurs, forms an almost impassable barrier between Burmese and Thai territory. The railway southward from Moulmein to Ye is continued by a road to Tavoy, but main access is still by sea. The Tavoy River is navigable for vessels of considerable size. It is interspersed with many islands and, with its numerous smaller tributaries, affords easy and rapid communication. In this southern part of Burma the climate is almost equatorial. The annual rainfall averages more than 200 in. (5,000 mm.). The staple crop is rice. Forests cover an area of nearly 5,000 sq.mi. (13,000 sq.km.).

Tavoy, with the rest of Tenasserim, was handed over to the British at the end of the first Burmese War in 1826. See further **BURMA**.

(L. D. S.)

**TAWNEY, RICHARD HENRY** (1880–1962), English economic historian and an outstanding social critic of his time, was born in Calcutta, India, on Nov. 30, 1880, and died in London on Jan. 16, 1962. He was educated at Rugby School and at Balliol College, Oxford. After social work in London at Toynbee Hall (q.v.), he became an active member in Rochdale of the Workers' Educational Association (WEA) and played an important part in its development, teaching tutorial classes at Oxford University (see **ADULT EDUCATION**) and eventually becoming president of the WEA (1928–44). While at Oxford he wrote his first major work, *The Agrarian Problem in the Sixteenth Century* (1912). Appointed to the London School of Economics in 1913, he became reader there in 1919 and was professor of economic history from 1931 to 1949, when he was made professor emeritus.

Tawney was an influential member of many economic boards and committees and became a valued governmental adviser. But his greatest contribution was to the work of the Labour Party (he was several times an unsuccessful Labour candidate). He urged greater state social investment, and many of his projects—raising the school-leaving age, extension of workers' education, and fixing of minimum wages—were effected. An ardent Christian and Socialist, he insisted that the basis of socialism was humanism. A good society could be built only by good men and not by dogmas or by merely changing the machinery of government. He condemned the acquisitiveness of capitalist society, which corrupted both rich and poor, as a morally wrong motivating principle. Tawney held that men want and need work not only for the income it provides but because they want to be creative and make a contribution to society. They can achieve a sense of fulfillment in their work only if they are convinced that it is important and serves some useful purpose. In capitalist societies, work was deprived of its inherent value, and, seen solely as a means to something else, it became drudgery.

Many of Tawney's books have become classics, notably *The Acquisitive Society* (1921), *Equality* (1931), and *Religion and the Rise of Capitalism* (1926), a study of the relation between Protestant thought and economic behaviour in the 16th and 17th centuries.

**TAXATION.** Taxes are compulsory levies for general governmental purposes. They include income taxes, excise taxes, tariffs, and a great variety of other types; they do not include

governmental receipts from borrowing, gifts, reparations, or various direct charges for special services.

Clear-cut lines among the various types of public revenue are hard to draw, and each type shades into adjacent classes. For example, in a twilight zone between taxation and borrowing are the compulsory loans levied by Canada, Great Britain, and the United States during World War II (in the form of refundable income taxes) and by Denmark and Israel in the 1950s. Also difficult to classify are social insurance contributions (not generally designated by law as taxes, except in the United States); they progressively take on the character of taxes as the relationship between the amount of the individual's contributions and the amount of his benefits is weakened by legislative action. Though generally thought of as a means of raising revenue, taxes are recognized also as a major instrument of national economic policy. In war or time of emergency, governments increase taxes to restrain inflation, and in time of depression they reduce taxes to stimulate the economy. When government spending equals one-fourth to one-third of the gross national product, as in Western Europe and North America, taxes play a crucial role not only as a source of revenue but as a balance wheel in the economy.

This article deals with taxation only in a broad, general sense and does not attempt to describe specific taxes in detail. (For special forms of taxes see the section on taxation in various country articles and also **CORPORATION TAX**; **EXCESS-PROFITS TAX**; **EXCISE TAX**; **INCOME TAX**; **LOCAL GOVERNMENT**; *Finance and Local Freedom*; and **TARIFF**.)

**History.**—Only late in human history did governments come to rely on taxes for the bulk of their revenue, especially on taxes levied equitably and with the consent of the governed. For centuries, the public domain was the chief source of public revenue, and taxation consisted largely of excises on domestic consumption and customs duties on foreign trade. It was the duty of the unprivileged classes—slaves, vassals, peasants, colonists, and conquered peoples—to support the ruling classes, whether they were the free citizens of Athens and Rome, the lords and nobles of the feudal barony, or the courtiers of Louis XIV. Taxes as a badge of freedom rather than a mark of bondage are a modern phenomenon.

In ancient Greece and Rome, income from mines, tribute from subjugated countries, gifts from wealthy citizens, and taxes on trade and consumption filled virtually all revenue needs. Except for Rome's famed inheritance and capitation taxes (both foreshadowed by ancient Egyptian taxes) and certain emergency levies in Greece, direct taxes on income and wealth were unknown.

Taxes of any kind had little place in the agrarian feudal system of the Middle Ages. The king, the duke, the count, the baron—each in turn derived income from the land he held directly and levied rentlike dues on those who held land at his pleasure, i.e., on those beneath him in the feudal hierarchy. From the 14th century on, as the feudal system was gradually broken up by dissipation of the public domain, by growth of industry and commerce, and by centralization of government, these patrimonial revenues slowly gave way to taxes.

Land, as the primary source of wealth, also became the primary source of taxation during this period. Both local and central governments in England turned to land taxes, basing them at first on area (the old *hidage* and *carucage*) but later on annual rental value. The French counterpart was the arbitrary annual *taille* on estimated farm income. The early American colonies broadened the British type of land tax into a property tax whose base included land, houses, personal property, and faculty (the rated earning capacity of one's trade or profession). With the great growth of foreign and domestic commerce between the 14th and 19th centuries, import and export duties and internal excises became important, especially in France, Spain, and other commercial centres. Poll taxes (levied at so much per head) and such levies as the hearth tax and window tax (both designed as rough measures of the taxpayer's wealth) also flourished in this period.

Rebellion against arbitrary and oppressive taxation played a major role in modern history. Such milestones in British constitutional history as the Magna Carta (1215) and the Bill of Rights (1689) helped establish the principle of consent and representation

in taxation. Failure to apply this principle to the colonies played no little part in the American Revolution. Much of the desperation that exploded in the French Revolution grew out of France's tax system—one of the most oppressive and inequitable tax systems of all time. The French government, as well as many others, followed the practice of turning over the collection of taxes to contractors known as tax farmers, who often employed harsh measures and aroused the hatred of the people. At the time of the Revolution the system was abolished, and many of the tax farmers were executed.

The establishment of representative democratic government, the advent of the industrial revolution, and the development of modern ideals of social justice and equality left their imprint on both the principles and the forms of taxation. The 19th century saw expediency and oppression in taxation gradually make way for equity and uniformity. With the unfolding of new forms and differentiated sources of wealth, taxes on incomes and inheritances were adopted and refined, and property taxes were further broadened.

Great Britain adopted an income tax in 1799 and a death transfer tax in 1796, broadened both measures (after setting the income tax aside from 1816 to 1842) midway through the 19th century, and brought them to something like their modern form near the turn of the century. Although customs and excises continued to be an important source of revenue, the central government during the first half of the 20th century greatly intensified its use of direct taxes on income and estates. "Local rates" on real estate continued to be the mainstay of local tax systems.

The United States did not make effective use of income and inheritance taxes until about the time of World War I. Before that time, tariffs, excises on liquor and tobacco, and sales of land furnished the bulk of federal revenues. The peculiarly American general property tax provided most of the revenues needed at the state and local levels. But during World War I and in the interwar period, the federal government adopted an estate tax, developed its corporate and individual income taxes, expanded its excises, and introduced social security payroll levies. The states meanwhile tapped such new sources as gasoline taxes, retail sales taxes, motor vehicle levies, and net income taxes, largely abandoning the property tax to the local units.

Under the pressure of World War II, central government taxes everywhere were brought to new peaks, both in their severity and in their adaptation to such nonrevenue ends as curbing of inflation and prevention of war profiteering. After the war, most belligerents granted only modest tax reductions in the face of large debts, continued inflation, and deteriorating relations between the major world powers. The outbreak of the Korean War in 1950 touched off a new wave of tax increases, but within three or four years, such countries as Australia, New Zealand, the United States, Canada, Great Britain, the Netherlands, and Germany were again reducing tax rates. In 1964 the U.S. Congress approved a substantial reduction in income and excise taxes, justified in part as a necessary stimulant for the economy.

**Modern Forms.**—As modern economic society progressively exposed new facets of wealth, income, and transactions, tax planners and legislators responded with a bewildering array of levies. The production and receipt of income, the ownership and transfer of wealth, the sale and use of commodities and services, the carrying on of a business, and a host of other economic factors all became bases or objects of taxation.

The versatility of income as a tax base can be visualized by observing the gantlet of taxes it may have to run as it flows into, through, and out of a corporation. At the point of entry, income may be subject to (1) taxes on gross receipts or gross income (often classed as consumption taxes because they are largely passed on to consumers in higher prices); (2) taxes on the net profits remaining after all expenses are deducted; (3) taxes on excessive profits, especially in wartime. Once inside the corporate walls, net income which is not distributed to stockholders may encounter taxes on undistributed profits. At the point of exit, income paid out as dividends may encounter a distributed profits tax like the post-World War II British tax of 30%. As it reaches the

stockholder, dividend income may be subject to (1) a progressive personal income tax applying a uniform schedule of rates to net income regardless of source; (2) a schedular income tax applying different rates to different sources of income; (3) a special tax surtax on investment income; (4) special credits or allowances under the regular income tax. To this galaxy of income taxes should perhaps be added the low-rate levies on business payrolls and individual wages so widely used to finance social security programs.

Property remains the principal local tax base in the English-speaking world. Broadest of all property taxes is the general property tax in the United States, an impersonal levy by local governments on both real estate and personal property, measured by exchange value and levied against owners. Narrower and more personal is the British system of local rates, confined to real estate, measured by annual rental value, and in part levied as a tax on occupants. Even narrower are the rural land taxes of Asia, the Middle East, and much of Europe.

Most personal of the taxes on property ownership are the progressive taxes on personal net worth (assets minus liabilities) levied in the form of (1) annual net worth taxes, as in Scandinavia, Germany, and the Netherlands; and (2) one-time capital levies, as in many European countries in the wake of both World Wars I and II. In the United States, constitutional barriers stand in the way of a national net worth tax.

Transfers of wealth by death are taxed in most Western countries under both estate taxes (levied on the decedent's estate as a whole) and inheritance, succession, or legacy taxes (levied on the heirs' distributive shares). Comparable taxes apply to transfers by gift.

Another major group includes consumption taxes, those which are generally passed on to consumers in the form of higher prices even though initially levied on producers or distributors. The term hidden taxes ordinarily refers to this group of levies. In their more general forms, they are levied as turnover, gross income, or value-added taxes at several stages of production; as sales or purchase taxes at the manufacturing, wholesale or retail stages; as use taxes on the consumer; and as tariffs or customs duties on imports and exports. In their more limited forms, they appear as selective excises on liquor, tobacco, gasoline, luxuries, and many other commodities and services; or as profits from government monopolies of salt, liquor, matches, tobacco, and the like.

Business taxes, in the broadest sense of the term, refer to all taxes arising out of the ownership and operation of businesses. More narrowly and usefully, the term refers to a separate category of taxes applicable only to business entities as such and bearing no relation to the personal status of the owners or operators of the business. In this sense, it includes on one hand such general privilege taxes as incorporation fees, capital stock taxes, the German *Gewerbesteuer*, and the French *patente*. On the other hand it covers levies which single out certain types of business for special taxation, e.g., in the United States the state taxes on insurance companies, usually measured by gross premiums, and on public utilities, measured by gross earnings or property. Corporate income and profits taxes are also often labelled business taxes.

**General Classifications.**—Tax literature and usage abound with general classifications. Apart from groupings by tax base or source, one of the most useful classifications is by type of effective rate structure, i.e., progressive, proportional, and regressive types. The distinction depends upon the ratio of tax liability to net income (or net worth). If the ratio rises as income rises, i.e., if the tax takes a greater percentage of a person's income, the larger that income—the tax is progressive. If the ratio is constant, the tax is proportional. If it declines as income rises, the tax is regressive. The terms are applied both to particular taxes and to tax systems as a whole. Among specific taxes, the personal net income, net worth, and death and gift taxes are almost universally progressive. Most property, sales, and excise taxes are levied at proportional rates but are regressive in effect; for example, a 5% sales tax takes a larger percentage of a small income than of a large income because the taxed items represent a larger percentage

of the small-income than of the large-income budget.

Another widely used distinction is that between direct and indirect taxes. A direct tax is one that tends to be borne by the persons upon whom the government levies it. An indirect tax is one that tends to be shifted, *i.e.*, passed on to others in the form of higher prices received or lower prices paid by the taxpayer. Since it is difficult to determine precisely who bears the final burden of a given tax, the line between the two is not easy to draw. Customarily classed as direct taxes are net income, net worth, death, gift, and land taxes. Consumption taxes, many business taxes, payroll taxes, and taxes on realty other than land are ordinarily considered to be indirect. Relative emphasis on direct versus indirect taxes as thus classified varies greatly from country to country.

Another useful distinction, encountered particularly in discussions of custom duties, is that between specific and ad valorem taxes. A tax or duty is specific when it is based on some physical measurement or quantity, *e.g.*, so much per pound, per yard, or per gallon. It is ad valorem when it is based on value and levied as a percentage of that value, *e.g.*, 15 mills per dollar (1.5%) of property value.

**Objectives and Criteria.**—The pervading objective of taxation, in concert with other government policies, is to promote the general welfare. Taxes contribute to this end by providing the financial foundation for the substantive functions of government and at the same time serving as an engine of social and economic betterment which nations can call upon to reduce excessive inequalities of wealth, to check inflation and war profiteering, and to promote economic stability.

How can the broad welfare objectives of taxation be translated into guideposts for tax policy? In the search for an answer, the maxims propounded by Adam Smith in his *Wealth of Nations* in 1776 provide a traditional point of departure. He set forth the tests of equity, certainty, convenience and economy as follows:

- I. The subjects of every state ought to contribute towards the support of the government, as nearly as possible, in proportion to their respective abilities; that is, in proportion to the revenue which they respectively enjoy under the protection of the state.
- II. The tax which each individual is bound to pay ought to be certain, and not arbitrary. The time of payment, the manner of payment, the quantity to be paid, ought all to be clear and plain to the contributor, and to every other person.
- III. Every tax ought to be levied at the time, or in the manner, in which it is most likely to be convenient for the contributor to pay it.
- IV. Every tax ought to be so contrived as both to take out and to keep out of the pockets of the people as little as possible, over and above what it brings into the public treasury of the state.

Appropriate as they were in his day, both as standards and as reform slogans in taxation, Smith's canons depend for their present-day validity largely on what is read into them. For example, Smith directed his maxim of certainty against the evil of lodging power over the amount and terms of taxes in the "tax-gatherer, who can either aggravate the tax upon any obnoxious contributor, or extort, by the terror of such aggravation, some present or prospective benefit to himself." In its modern context, the demand for certainty is usually a protest against too frequent changes in tax laws, regulations and court decisions. Moreover, the unfolding of the principle of progression in taxation has infused new meaning into Smith's maxim of equity. Even with modernized content, however, his canons furnish little more than three common-sense rules of tax administration and one basic principle, that of equity, for the distribution of tax burdens.

That this set of guides is no longer adequate is hardly surprising in view of the sweeping economic, social and political developments since Smith's day. Concepts of justice have changed profoundly. Methods of measuring economic strength have been refined. Democratic control of taxation has been won. Tax administration has vastly improved. Economic systems have become enormously more complex and interdependent. The sense of social responsibility and, with it, the role of government have steadily grown. In response to these changes, it was inevitable that the functions of taxation should be broadened and its standards recast. As adapted to modern circumstances, the canons may

be re-examined under four major headings: (1) social justice; (2) consistency with economic goals; (3) ease of administration and compliance; and (4) revenue adequacy.

**Social Justice.**—That taxes should be just is a self-evident first principle of taxation. But in taxation, as in other fields, justice is a product not of scientific analysis but of a people's value judgments. As reflected in contemporary tax systems, the value decisions modern societies have made regarding social justice appear to require: (1) that taxes be impartial in their application—the "equity" test; and (2) that taxes, on balance, be designed to reduce economic inequalities—the "equality" test. Unfortunately the precise meaning and the practical dictates of these tests are not readily definable and have, in fact, been the subject of extended controversy.

It is, to be sure, widely agreed that equity in taxation requires impartial (not identical) treatment, *i.e.*, equal taxes on persons in like circumstances and reasonably differentiated taxes on persons in unlike circumstances. Thus, the equity criterion sets up the presumption that even when taxation is asked to serve such external ends as redistribution of income or recapture of excessive war profits, the internal structure of the taxes levied should adhere to the principle of reasonable classification and impartial treatment. But the nub of the problem is: What is reasonable classification in taxation—what characteristics of a person identify him with or differentiate him from other persons for taxing purposes? And once acceptable criteria have been developed for classifying people, what relative tax burdens should the different classes bear?

For a limited group of levies on the border line of taxation, it has been deemed equitable to classify people and tax them according to the quantity of benefits received from government. Where such benefits can be identified and measured, at least roughly, and the social interest does not demand a subsidy to the individual or group benefited, it is reasonable to apply the benefit principle. Gasoline taxes and social security employment levies are commonly justified on the ground that special benefits—the use of the highways and protection against insecurity—accrue to the taxpayer in more or less direct proportion to the amount of tax he pays.

But the difficulty of measuring most government benefits and the desirability of providing many services on the basis of need narrowly limit the application of the benefit principle. And the day when "taxation according to benefits received" was a battle cry in the struggle to shift the yoke of taxation from the overburdened masses to the exempt nobility has long since passed.

Accordingly, the principle of ability to pay is generally invoked as a basis for classifying and differentiating among people for tax purposes. Deceptively simple in appearance, this concept involves many difficulties of application. At the outset, one notes that ability to pay as such is subjective, an attribute of persons, not things. Yet its measure for tax purposes is necessarily objective, an external quantity such as income or wealth. An individual's ability may be gauged by his flow of income or spendings over a certain unit of time or his stock of wealth at any given time. Net income is widely recognized as the best index. But the amount of net income is only one element in the measurement of ability. Individual income tax laws also take into account (1) family obligations, recognized in marital and dependency exemptions, and (2) less universally, the source of the income, recognized in differential treatment favouring "earned" over "unearned" income. Even after this yardstick, properly calibrated, ranks individuals according to their income, the question remains as to how much more the person of high rank should pay than the one of lower rank.

Except for one or two fleeting references to progression, Adam Smith answered that taxes should be proportional to income. Nearly 75 years later, the Scottish economist John R. McCulloch still held, "The moment you abandon . . . the cardinal principle [of proportion], you are at sea without rudder or compass, and there is no amount of injustice and folly you may not commit." Expressing the predominant modern view, F. W. Taussig replied that only through progression could democratic ideals of justice in taxation be achieved. As to the lack of precise standards for de-

termining the degree of progression, E. R. A. Seligman added that it is better to approximate justice than to be clearly unjust.

While progression is, in practice, essentially a 20th-century phenomenon, it is interesting to note that the Indian sage Manu recognized the principle more than 3,000 years ago in these words:

"To make the burden of taxes equal . . . is not effected by a mere numerical proportion. The man who is taxed to the amount of one-tenth . . . of an income of 100 rupees per annum, is taxed far more severely than the man who is taxed an equal proportion of an income of 1,000 rupees, and to a prodigious bigness more severely than the man who is taxed an equal proportion of 10,000 rupees per annum."

In the development of ability-to-pay theories of progressive taxation, the "sacrifice" doctrines have played a major role. An offshoot of hedonistic or utilitarian economics, these doctrines find their most refined expression in A. C. Pigou's least-sacrifice theory. It holds that progression is necessary to minimize the aggregate direct burden of taxes on individuals. The theory stands or falls on the validity of its assumptions (1) that different people are about equally efficient as "pleasure machines," i.e., that they have similar capacities for satisfaction, and (2) that the marginal utility of money diminishes as income increases, i.e., that as an individual's income rises, the want-satisfying value of each additional unit of it falls. If these assumptions are valid, it follows from (2) that the larger the income, the smaller the sacrifice in giving up a unit of it in taxes, and from (1) that the relation between income and sacrifice is similar for different people. Minimum sacrifice thus calls for progressive taxes which bear heavily on the less important units at the margin of large incomes and lightly on the more important units at the margin of small incomes.

Modern welfare economists question the stated assumptions, pointing out that they cannot be verified until a way is found not only to measure satisfactions but to compare them among different people. They are therefore disinclined to accept a defense of progression which is based on sacrifice doctrines.

Not satisfied with attenuated translations of "ability to pay" into "progression," many noted thinkers have rested their case for progressive taxation simply on a desire to reduce inequalities in wealth and income. Adolph Wagner argued in *Finanzwissenschaft* (1880) that defenses of progression on the basis of ability to pay become meaningful only in terms of greater economic equality. In his view, reducing inequality of incomes increases the general welfare by enabling more urgent needs to be satisfied at the expense of less urgent needs. Taussig's later use of the equality criterion was based mainly on his interpretation of the democratic consensus that "... such great degrees of inequality as the modern world shows are regarded as not consonant with canons of justice." Henry C. Simons, writing in the 1930s, stated also that the case for sharp progression must rest on the ethical judgment that the prevailing degree (and/or kind) of inequality in wealth and income is "distinctly evil and unlovely."

**Consistency with Economic Goals.**—The importance of harmonizing the economic overtones of taxation with the economic goals of the community—seen as efficient allocation and full employment of resources, rising living standards and economic stability—has long been recognized. But the concept of using taxes actively to promote a stable economy and full use of resources gained currency only toward mid-20th century, largely through Lord Keynes and his followers. Every tax became recognized as affecting the spending power and propensity of taxpayers as consumers and producers and their incentives to exert effort and initiative as workers, managers and investors. The ideal tax structure thus is one which (1) restricts private spending during inflation and expands it during depression and (2) interferes least with, or perhaps even stimulates, effort and risk taking.

The health and growth of a modern industrialized economy depend upon an adequate volume of demand for the goods and services it is capable of producing when fully employed. Whether that demand will be forthcoming depends on the aggregate spending of consumers, businesses, and governments. When income is withdrawn from the spending stream by individuals who neither spend it nor invest it (or by businesses which neither distribute

it nor spend it on inventories, plant, and equipment), the net result is to dry up demand and employment. Alternatively, when individuals and businesses as a whole run deficits and augment their spending by borrowing money or drawing on assets, the result is to inflate demand and employment. Left to itself, the private economy will experience cyclical slumps and booms. In this setting, it is desirable that central governments use taxes as part of a coordinated fiscal-monetary policy to stabilize the economy.

Tax policy in this context has to concern itself, first of all, with the cyclical stability of total spending. Flexible taxes serve as one means of resisting or correcting its instability, of restricting total spending in a boom period and expanding it in a slump. This approach calls for a tax system and a tax policy which increase tax collections relative to expenditures in booms and decrease them in depressions: It applauds progressive income taxes, whose revenues automatically expand and contract more than in proportion to the ups and downs of national income; current collection and withholding magnify this stabilizing impact by making tax revenues respond instantly to changes in income. Contracyclical tax policy also enlists short-term changes in tax rates to impound or free purchasing power. The British White Paper on Employment Policy (1944) stated that "the ideal to be aimed at is some corrective influence which comes into play automatically—on the analogy of a thermostatic control . . ." and suggested "variation of rates of taxation and the incorporation of some system of deferred credits (repayable in bad times) as a permanent feature of national taxation." In accord with this suggestion, the government adopted a "tax regulator" law under which it could move the rates of certain payroll and consumption taxes up and down against the grain of the business cycle.

Unless contracyclical tax measures are already imbedded in the law, tax increases to combat inflation and tax decreases to counter deflation may be unduly delayed in the legislative and administrative process. This is especially likely in the U.S., where tax proposals by the executive do not have the thrust provided by parliamentary systems under which the government in power stands or falls on the acceptance or rejection of its program.

Under the U.S. system, the executive proposes but the congress disposes—often slowly and only after successive modifications by the house of representatives through its ways and means committee, by the senate finance committee, by the senate itself and finally by the joint conference committee. Nonetheless, in severe economic fluctuations, it may be necessary to reinforce automatic variations in revenues with discretionary changes in tax rates to generate the required anti-inflationary surpluses or expansionary deficits. To overcome the possible delay inherent in the U.S. system, the president in 1962 recommended to the Congress enactment of "stand-by authority" to permit a quick temporary across-the-board reduction in individual income tax rates to cope with recessions. Congress did not respond to this recommendation, and in 1965 a far milder presidential proposal urging Congress to ensure "that its procedures will permit rapid action on temporary income tax cuts if recession threatens" got no immediate congressional response.

In contrast with the wide area of agreement among economists on the broad principles of anticyclical tax policy, there is no consensus on whether tax systems should be biased toward stimulating or damping down total spending in the long run. For the classical economists of an earlier age, this was no problem. Full employment was largely taken for granted, and savings were seen as the key to progress, as an unmixed blessing to be disturbed as little as possible by taxes, especially progressive taxes. But the great depression of the 1930s raised the spectre of the mature or stagnant economy, beset with persistent unemployment, weak markets, redundant savings, and lagging investment. It suggested to Keynes and his followers that tax policy coupled with government expenditure should seek to activate dormant purchasing power and increase the flow of spending. This would call for taxes which bear heavily on the private incomes least likely to be spent and lightly on those most likely to be spent. To the extent that high incomes are less likely, and low incomes more likely, to be spent by their recipients, progressive taxes would be welcomed under these circumstances.

Under the impact of World War II, the feared circumstances did not materialize. In fact, the economic record of the first decade after the war suggested that, at least under conditions of armed peace, the problem of containing chronic inflation might replace the problem of sustaining aggregate demand. In the second decade after World War II the picture changed again. In the United States, the slow rate of economic growth in the late 1950s, the unsatisfactory recoveries after the 1957-58 and 1960-61 recessions, and the persistence of substantial unemployment pointed to the desirability of comprehensive tax reduction and reform to spur the economy's advance. After considerable delay in the legislative process, a huge tax cut was enacted in 1964. Together with the 1962 measures, this action reduced both individual and corporate income taxes by nearly 20%. Excise taxes were sharply reduced in 1965. All told, the 1961-65 actions reduced tax liabilities by more than \$20,000,000,000 in a successful effort to remove the "fiscal over-burden" which had been retarding the advance of the U.S. economy. The success of the tax cut in stimulating the economy to new heights led to a new acceptance and understanding of fiscal policy in the United States.

Taxation is often called upon to serve economic ends other than those concerned with aggregate spending and saving. Taxes are employed to subsidize the production of certain items, e.g., protective tariffs, and to penalize the production of others, e.g., the heavy taxes levied by dairying states on oleomargarine. In World War II, high excises were imposed on automobiles and radios to divert resources from their production into war production. The elimination of unwarranted economic gain from war has been a primary objective of excess profits taxes (g.v.). Taxation has thus come to be widely used as an instrument of indirect economic control.

A novel provision for stimulating investment in new machinery and equipment was enacted by the U.S. Congress in 1962. It granted business a 7% tax credit for investment in certain depreciable property. The purpose was to reduce the risk and increase the profitability of new investment and improve business liquidity, which is of particular importance for new and smaller firms.

**Ease of Administration and Compliance.**—The exacting requirements of social justice and economic harmony in taxation are necessarily tempered by considerations of administrative efficiency and taxpayer convenience. Unless a tax can be administered at a reasonable cost to both government and taxpayers and without large-scale evasion by illegal means and avoidance through legal loopholes and subterfuges, it becomes unworkable no matter how laudable its economic and social objectives. The sense of equity is as surely violated by a tax which applies unequally to taxpayers in identical circumstances because of lax administration as it is by a tax which is basically unfair in its statutory provisions. From the standpoint of administration and compliance alone, taxes should be simple to compute and easy to understand (understanding being a matter of the concepts and tax returns which confront the taxpayer), assessed on an obvious base easily arrived at, levied at moderate rates, and payable in a convenient manner.

But the degree of simplicity required or of complexity permissible is not an absolute. Much depends on the nature of the tax; for example, the minimum complexity required to bring about tolerable equity in an excess profits tax is much greater than that required in a tobacco tax. Much also depends on the scope of the tax—how widely it applies and how deeply it cuts. The demands for ease and simplicity of the United States individual income tax were far less pressing at the end of the 1930s, when it applied at moderate rates to 4,000,000 persons, than during World War II or in the mid-1950s, when it applied at heavy rates to more than 50,000,000. Factors external to a given tax must also be taken into account. The lack of coordination of federal, state, and local tax systems, for example, imposes costs and irritations arising not out of a particular tax but out of the conflict and duplication among taxes and taxing jurisdictions. Even more important are the factors external to the tax system as a whole. The general level and standards of the civil service establish a boundary beyond which taxes cannot go in the direction of refinement and complexity. Administrative techniques and competence, in turn, depend in good part on the stage of development of society. A coun-

try that is sparsely settled and industrially undeveloped is likely to have very simple administrative machinery and therefore to rely heavily on taxes with an easily discoverable base, e.g., land taxes and taxes on imports and exports. In more advanced countries, the machinery and the economic data on which it depends are better geared to direct, personal taxes, such as those on incomes. Level of public education, attitudes toward government, and concepts of tax justice are likewise vital in determining how complicated a tax may be without jeopardizing its success.

**Revenue Adequacy.**—The receipts of government must be sufficient to commandeer for the state that part of society's real resources which social and economic policy wishes to devote to collective use. Traditionally, it was demanded that taxes alone free the necessary resources for collective use each year, i.e., balance the budget annually. This position was later modified to permit deficits in bad years, provided they were offset by tax surpluses in good years, i.e., provided the budget were balanced cyclically. Many modern economists have abandoned the idea of a balanced central government budget as an end in itself. Their goal is a balanced economic budget for the nation, sufficient total spending to balance and sustain the income flowing from production and employment. After World War II, the British, Canadian, and, to a lesser extent, the United States government budgets were presented in the perspective of the national economic budget.

In this conception, taxes are not levied for revenue alone. The test of adequate yield as applied to the tax system is not that it cover a predetermined level of government expenditure but rather that, together with borrowing if necessary, it raise the required funds in the manner best calculated to further the end of full and stable employment. The quantitative role of taxation becomes interlocked with its qualitative role.

This reasoning applies primarily to central governments. Their fiscal policies may appropriately be designed to offset tendencies toward economic instability in the private sector of the economy. But for local governments, more closely analogous to private persons, taxation remains primarily a means of raising revenue. In the United States, for example, local governments differ from the central government in that they lack money and central banking powers, their debts are held externally, and they have neither the ability nor the responsibility to maintain high levels of employment. In this context, the traditional aims of stable tax yields and at least cyclically balanced budgets remain valid.

**Shifting, Incidence, and Effects.**—To know only who bears the impact of a tax, i.e., who turns the money over to the government or its agents, is to know very little indeed about the social and economic consequences of that tax. The tax may set loose forces which enable the original payer to obtain higher prices for the goods or services he sells or pay lower prices for those he buys, thus giving him relief through shifting. The tax may also affect both private and governmental consumption and investment and hence the national income. To pass final judgment on a tax, one needs to know how it affects the distribution of real income available for private use, called its incidence, and what repercussions it has on the level of national income, called its effects.

Unfortunately, the way in which a tax affects the distribution and level of income cannot be isolated for precise statistical study. Since conclusions must perforce be reached largely through deductive processes combining reasonable assumptions with analysis of economic forces, the theory of incidence and effects is heavily dependent on the economic theory of price and income determination. A fairly general consensus on the incidence of the major taxes has been tentatively reached along the lines indicated above in the classification of taxes into direct and indirect.

**Comparative Revenues and Burdens.**—Valid international comparisons of tax burdens or tax rates are difficult to make. Comparisons of tax rates or per capita taxes are especially likely to be misleading because of differences in purchasing power of money (not reflected in exchange ratios), in standards of living, in distribution of income, etc. Even the ratios of taxes to national income or product—most widely accepted as a reliable index of comparative burdens—do not tell (1) whether taxes equaled, exceeded, or fell short of government spending and (2) whether the

governments spent the proceeds wisely in terms of efficiency and honesty of administration and effectiveness in gauging and following the preferences of the body politic.

**TAXICAB:** see MOTOR TRANSPORTATION.

**TAXODIACEAE**, a small but very important family of cone-bearing plants, including some of the largest trees known. The California redwood and the other American and Oriental genera are important timber trees. Many species are planted for ornament.

The genera customarily recognized are: *Sciadopitys* (umbrella pine), *Sequoiadendron* (big tree), *Sequoia* (coast redwood), *Metasequoia* (dawn redwood), *Taxodium* (bald cypress), *Glyptostrobus*, *Cryptomeria* (Japanese cedar or redwood), *Athrotaxis*, *Taiwania*, and *Cunninghamia*. All occur in the Northern Hemisphere in America, Asia, or both, except the genus *Athrotaxis* from Tasmania. The trees have scale-like or needlelike leaves, often in frondlike branchlets.

The staminate, or pollen-bearing, cones are solitary (terminal or axillary) or clustered; their spirally arranged scales bear three to nine pollen cases, or sporangia. The ovulate, or seed-bearing, cones are solitary and terminal on a branch and are composed of many spirally arranged scales fused more or less completely with the bract, which becomes thick and woody; their two to nine seeds are erect in some genera and inverted in others. Embryogeny in the family ranges from the extreme type of cleavage polyembryony in *Sciadopitys* to the rather advanced form in *Sequoia*. The number of seed leaves, or cotyledons, varies from two to eight. For details on structure and life cycles, see **CONIFERS**. (R. W. H.)

ADAPTED FROM G. LAWRENCE, "TAXONOMY OF VASCULAR PLANTS," 1961, THE MACMILLAN COMPANY, NEW YORK

REPRESENTATIVE SPECIES OF THE FAMILY TAXODIACEAE

commonly used to distinguish plants from animals, see **ANIMAL** and introductory paragraphs of **PLANTS AND PLANT SCIENCE**. Main subordinate groups are successively the phylum (or division for plants), class, order, family, genus, and species.

In the following table the scientific "credentials" of a paramcium, a pine and a dog illustrate the seven basic (obligatory) taxonomic categories that are used to identify and classify organisms. Each lower taxon is part of the larger taxon that precedes it.

Kingdom	Protista	Plantae	Animalia
Phylum	Protozoa	Tracheophyta	Chordata
Class	Ciliata	Pteropsida	Mammalia
Order	Holotricha	Coniferales	Carnivora
Family	Parameciidae	Pinaceae	Canidae
Genus	Paramecium	Pinus	Canis
Species	Paramecium caudatum (paramecium)	Pinus nigra (black or Austrian pine)	Canis familiaris (any breed of dog)

In many cases need has arisen for a more precise definition of the taxonomic position of an organism to express a finer degree of relationship of the component groups. Traditionally, this has been effected by splitting the original taxa and then inserting a newly formed category; e.g., it has been found necessary to insert super- or sub-categories, such as the subclass Gymnospermae (or Gymnospermae) between Pteropsida and Coniferales in the plant column above, and the subphylum Vertebrata between Chordata and Mammalia in the animal column.

Here is a generally accepted complete list of the taxa that a specialist in systematics might use:

Kingdom  
Subkingdom  
Phylum (or Division for plants)  
Subphylum (or Subdivision for plants)  
Superclass  
Class  
Subclass  
Infraclass  
Cohort  
Superorder  
Order  
Suborder  
Superfamily (-oidea)  
Family (-idae for animals, -aceae for plants)  
Subfamily (-inae)  
Tribe (-ini)  
Genus  
Subgenus  
Species  
Subspecies (Variety for plants)

Endings are standardized only for names of tribes, subfamilies, families, and superfamilies as shown above in parentheses. Thus, a complete taxonomic identification of the dog would be:

Kingdom Animalia  
Subkingdom Metazoa  
Phylum Chordata  
Subphylum Vertebrata  
Superclass Tetrapoda  
Class Mammalia  
Subclass Theria  
Infraclass Eutheria  
Cohort Ferungulata  
Superorder Ferae  
Order Carnivora  
Suborder Fissipeda  
Superfamily Canoidea  
Family Canidae  
Subfamily Caninae  
Tribe (none)  
Genus Canis  
Subgenus (none)  
Species Canis familiaris  
Subspecies (none)

In addition, breeders would add further breed designations, not considered true taxa, such as "collie," "German shepherd," "cocker spaniel," etc. (In some cases certain taxa are not used; in the dog, for example, there is no need for tribe, subgenus, and subspecies designations.)

**Importance.**—The purpose of taxonomy is to develop a com-

venient and precise method of classifying knowledge that conforms to fundamental principles of biology. The role, then, of taxonomy, or systematics, is to rank categories in a hierarchical system. The function of nomenclature is merely to determine what an organism is to be called, what its scientific label should be. The need for naming the categories (many of which are recognized in common speech) produces an intimate relation between taxonomy and zoological and botanical nomenclature. The taxonomic name provides an index symbol to the biological literature containing all recorded information about the species or group.

Taxonomy depends on descriptive biology for most of its materials, but descriptions of plants and animals, and most alterations of the system of classification, are now made within the framework set up by the taxonomists of the past. This framework is the slow growth of two centuries of proposal and critique. Some taxonomic problems are subject to experiment, and taxonomy does not rest upon descriptive morphology alone. Structure, however, is an indication of subtle genetic, physiologic and growth processes, so much progress depends upon correlations of structural differences and similarities. In the pre-Darwinian era, the categories of the classificatory system (especially the species and genus) were thought of as reflecting some mystical relation to the ideas of the Creator. In the light of evolutionary theory (see *EVOLUTION, ORGANIC*), the classification of organisms tends toward a more and more exact reflection of their natural relations; i.e., of their phylogeny (see *ANIMALS, PHYLOGENY OF*).

Modern taxonomy depends upon the reproduction of basic genetic homology (see *HOMOLOGY*) through evolutionary time together with modification by means of genetic mutation, recombination, reproductive isolation and natural selection. All life, so far as is known, is interrelated and genetically continuous in the past, and all life has undergone adaptive evolution and branching of taxonomic groups in geologic time. A few living species have not changed sufficiently to require taxonomic reassignment since Mesozoic times (ending more than 70,000,000 years ago), and several living genera are recognized from fossils in Triassic deposits (over 160,000,000 years old). One living genus of brachiopods (*Lingula*) is known from fossil shells of Ordovician age (about 350,000,000 years old).

**Method.**—The basic method of taxonomy is to compare and weigh the characteristics of the structure of plants and animals by the methods of comparative anatomy, and to interpret the major subdivisions in the light of comparative genetics, biochemistry, physiology, embryology, behaviour, ecology and geography. Systems of classification based upon a single set of characters, or drawn up from a single viewpoint, must be reinterpreted by the study of all available knowledge of the forms concerned.

Classification may begin purely as a matter of convenience, as was the case with early botanical classifications, which developed in association with the use of herbs and plant products in medicine. Such classification based on the more superficial distinctions rather than on the more fundamental similarities and differences is termed artificial. (See *BIOLOGY: Methods of Approach*.) The distinction between an artificial and a natural classification was necessarily obscure in the century before Darwin.

The basic units of the classificatory system are readily recognizable kinds or species (see *SPECIES: Biological Species*) of plants and animals. Some of these are distinguished in common knowledge, like the horse and the ass, or white oak and red oak. These instances also illustrate the first step in the process of classification, the grouping together of the various single-hoofed animals related to the horse (horse, ass and zebra) as the horse genus, *Equus*, and similarly the grouping of acorn-bearing trees into the oak genus, *Quercus*. By the simple device of combining the name of the genus with that of the species, the resulting names indicate the relationships and allow for additional species to be included when discovered. The technical scheme of generic and specific names in Latin, established by Linnaeus in the mid-18th century, has proved satisfactory and has in fact greatly stimulated the exploration of the world for the distinguishable kinds of plants and animals.

The merit of the Linnaean system lies in its suitability for con-

tinued correction, as well as expansion, in the light of increasing knowledge, without loss of its essential character. A large proportion of our knowledge of plants and animals comes to be correlated with the system of classification. The amplification and correction of the classification is a continuing active function of taxonomic research.

**Species and Genera Concepts.**—Definition of species as "an evolved (and probably evolving), genetically distinctive, reproductively isolated, natural population" is analytical, practical and understandable in the light of biological theory. Different species populations, whether sexual or asexual, have different genetic characters that may be detected by quantitative incidence of genes, qualitatively different genes, polygenic characters, or chromosomal changes in arrangement and numbers, all of which are reflected in the structure or the living activity of the component individuals.

It is estimated that more than 300,000 plant species and more than 1,000,000 animal species have been named. Descriptions of newly discovered species add between 15,000 and 20,000 each year. Over half of the known species of plants and animals are insects (class Insecta), and about one-third of all known species of animals are beetles (order Coleoptera). There is probably no single species of living or extinct plant or animal that is of no importance to man, either economically or for his basic understanding of organic nature.

As the knowledge about the variability of species increased, and when species began to be studied as populations, it was realized that the collecting of specimens constitutes only a method of sampling. A subordinate category, the subspecies, was established for series of organisms only partially reproductively isolated and often connected by transitional (or intergrading) populations.

Geographic gradients of variation, either uniform or separated by "steps," as topographic, climatic or other barriers reduce genetic exchange, form an important aspect of variation within species. Such gradients of variation are termed clines, and those in which there are interruptions or irregularities are referred to as step-clines. To distinguish as named subspecies the segments of a uniform variation gradient (particularly of a single character) appears to be fallacious. The segments of a sloping step-cline, however, may correspond exactly to a series of subspecies defined on other grounds.

The subspecies of zoological systematics is defined most often on a geographic and ecologic basis, and is derived from the Linnaean concept of variety subordinate to the species. Variety, as a term, has been used to cover so great a diversity of variation, equally including mutation, phenotypic variation and geographic form, as to be useless in a precise taxonomy. Transition to the subspecies concept in botanical nomenclature has lagged behind that in zoology. A great variety of infraspecies terms has been proposed, and is useful in the analysis of variations and evolutionary process.

Turning again to the species level, a most important clarification of the concept lies in the recognition that purely morphological definition must be subordinated to the concept that the species is composed of populations in which variability is inherent. The "closet naturalist" (without experience with living populations in their natural habitat) was exposed to the fallacy of describing variant individuals as species. Much of modern taxonomic investigation is occupied in the re-evaluation of the work of earlier taxonomists by means of more adequate collections, anatomical study, and concepts from the fields of genetics, embryology, physiology, ecology, psychology and geography.

Re-examination on the basis of larger collections (i.e., a representative sample) may unite a whole series of supposedly distinct forms into one, or may separate distinct forms that had long been included in a single variable species. A few species have now been subjected to comprehensive genetic analysis, especially among the fruit flies of the genus *Drosophila*, and such analysis throws much light on taxonomic problems.

The morphological characteristics distinguishing genera are ordinarily (but not necessarily) more sharply defined than those distinguishing species, and the distinctions between genera are regarded as having an origin more remote in time than those be-

tween their included species. Thus the concept of the genus comes to have especial importance in paleontology (*q.v.*). The genetic and biochemical reality of the genus or other more inclusive taxonomic category is attested by instances in which one species of parasite, symbiote or predator is associated exclusively with several species within a single genus, or several genera within a single family.

So many genera are familiar in ordinary thought and language, like the oaks (*Quercus*), the maples (*Acer*), the cats (*Felis*), some of the squirrels (*Sciurus*), etc., that there should be no difficulty in the wider application of the concept of the genus as a natural group of related species. Definition of genera by means of characters thought to be of generic value may lead to an arbitrary and unnatural assortment of species. The synthetic assortment of known species into their evident groups, as if they were building blocks, thus becomes an extremely important check on generic classification. It has been discovered that characteristics suitable for the definition of genera in one group may be useful only in the distinction of species in another. When the number of species of a genus is large, these may fall into subordinate groups, which are referred to as subgenera. When a single species has a number of sharply distinctive characters separating it from a related group of species within a genus, it may be placed in a monotypic genus by itself.

Study of fossil remains of both plants and animals obviously introduces the dimension of time into variation, and this affects all of the categories, and would complicate the distinction of the groups of lower rank even more were it not for the fact that the interruptions in the paleontological record supply convenient gaps between species and genera. As paleontological data accumulate, important modifications of the classification of the higher groups become necessary (*see below*).

Geographic series of subspecies, connected by intergradation where they meet, or similar series with overlapping variation (as on chains of islands), are matched by series of geographically representative but fully distinct species. Ecological differences in the habitats of the component members of such series has led to local adaptation. When former geographically separated species have been brought together by a breakdown of the barriers between them, the two species may form a hybrid population, one species may eliminate its competing relative, or each may occupy different ecological niches in the same region. Ernst Mayr clarifies this problem by the distinction of species as sympatric, if their areas of distribution overlap, and allopatric, if their geographic ranges are distinct.

**Higher Categories.**—Just as well-known sharply defined species and readily recognizable genera serve to introduce the words "species" and "genus" in the more precise sense of taxonomy, common knowledge is reflected in the language for some of the larger divisions at the other end of the system of classification. The primary division, into the plant and animal kingdoms, appears in various languages. A few groups like the sponges, mollusks, insects, birds and ferns, correspond rather precisely with the more exact zoological and botanical categories.

The taxonomy of the higher groups may be pursued analytically, beginning at the top and searching for the successive subdivisions of the two kingdoms, or it may be studied by the synthetic method, beginning with the more factually defined groups nearer the bottom of the scale, and especially with the genera. The arrangement of the groups above the species level has been improved by additional information from many sources, particularly from paleontology, comparative anatomy, embryology and ecology. Related taxonomic groups of whatever rank may be presumed to share varying degrees of genetic identity by means of descent from common ancestry, and the ranking of taxonomic categories is at least roughly correlated with the comparative number and complexity of shared homologous characters.

The difference between an artificial and a natural classification of the higher groups rests primarily on the distinction between analogy and homology. The discernment of both homology and analogy in the structures of animals closely or remotely related, forms the contribution of comparative anatomy to taxonomy.

Because homologues and analogues may be associated in the same structure, the practical distinction may be far from simple. As wings, the wings of a bird and of a bat are analogous and not homologous; *i.e.*, they must be presumed to have arisen independently and not one from the other. As fore-limbs, the wings of a bird and those of a bat are plainly homologous, as they are associated with the arm of man or the foreleg of an elephant, and support other evidence as to the relation of these several forms within the subphylum Vertebrata. In a broad sense, homology may be of quite a different type, like the correspondence between the alternating generations of ferns and flowering plants so brilliantly demonstrated by W. F. Hofmeister.

Homology of structures predicates the common inheritance of the characters under consideration, while independently derived analogous structures that resemble each other are said to be convergent (*i.e.*, the wings of birds and insects). Independently derived functional adaptive evolution of a basically homologous character (*i.e.*, the stiff tail feathers of woodpeckers and creepers), or independently evolved vestiges of a formerly adapted homologous structure (*i.e.*, the reduced eyes of cave fishes and cave salamanders), are often referred to as examples of parallel evolution.

The successive subordination of the series of groups, with steadily increasing number of the lower categories in most types (not in all) is reflected in the familiar comparison with a branching tree, with its trunk, main branches, smaller branches and finally twigs. Actually when the major groups are traced backward in the light of paleontology, the origins prove to be remote in time and apparently close together, and one is tempted to write of a phylogenetic "selaginella" or "fernclump" rather than of a "tree." Thus all of the main groups of living mammals trace back to the Early Tertiary or Late Cretaceous, and most of the principal groups of animals, the phyla, appear in the earliest known fossil-bearing strata of Cambrian age approximately 550,000,000 years old.

The exact relations of branch to branch or of branch to trunk are often unknown, being for the most part lost in the imperfections of the paleontological record. There are accordingly numerous groups at every level in the classification that are regarded as equivalent, and much effort has been expended to make them reasonably so. It may be pointed out that much difference of opinion over taxonomic groups in general applies to their rank in the hierarchy rather than to their validity as definable groups.

Many of the intermediate categories, especially the orders and families, are essentially the resultant of evolutionary specialization in a single direction (like the orders for the ichthyosaurs or whales, or the family of sea snakes). A different type of order or family is represented by a group that retains (or reacquires) the capacity for divergence into several major types of environment (*i.e.*, terrestrial, subterranean, arboreal and aquatic), and whose members thus compete with a wide variety of other animal types for specific ecological niches. Examples are supplied by the order Rodentia, the Saurischian dinosaurs, or the weasel family, the Mustelidae. Thus the adaptable or pliant group is often sharply distinguished from the specialized or end group. This involves a generalization as to the "irreversibility of evolution." Complex identical genetic patterns never originate twice nor, if lost, ever appear again in evolutionary history. Parallel mutation of genes and chromosomes may be repeated, but almost all taxonomic characters are genetically far more complex. Still another example of nonequivalent categories is evident in the difference between the grades "order" and "family" in an ancestral group like the Reptilia, and a derived group such as the Mammalia.

A major problem is introduced by paleontology in groups in which the evidence of ancestral approximation (at the point of divergence of the branches of the phylogenetic tree) has been discovered. The various genera close to the point of origin may either be associated with their later derived and more distinctive descendants, in a vertical classification, or with the primitive forms of the other branches to which they may be more closely similar in actual morphology, in a horizontal classification. This antithesis of phylogenetic and morphological definition of groups is notably exemplified by the Early Tertiary ancestry of horses, rhinoceroses

and tapirs. In both types of classification, the more inclusive taxonomic categories are monophyletic and are presumed to have originated from a single ancestral species.

The tendency to give equal importance to all comparative characters of organisms often leads to bias and to errors of judgment. Because the order of taxonomic classification is based upon homology through descent, principles of evolution are both substantiated by taxonomic data and, in turn, may be used for taxonomic interpretation. For example, it is possible to distinguish homology from analogy and both from fortuitous resemblance, strongly adaptive from weakly adaptive or nonadaptive characters, primitive from derivative characters, rapidly evolving from slowly evolving characters, persistent conservative characters from labile changing characters, qualitative from quantitative characters, progressively functional characters from regressed vestiges, relatively complex from relatively simple characters, and individually acquired characters from hereditary characters.

**Relationship to Other Sciences.**—Since some classification is essential for the establishment of scientific botany and zoology, taxonomy in its origins is one of the most elementary of disciplines. The record-keeping function of taxonomy affords an essential continuing service to all of the biological sciences. As these have grown to maturity, they have returned to draw problems and insights from the parent science, and the parent taxonomy has been infused with new interest from the light thrown upon its material and its categories by comparative genetics, embryology, physiology, ecology, biogeography and behaviour. The synthetic science of ecology, growing out of the older less critical natural history, depends implicitly on sound development of systematic botany and zoology.

Future taxonomic progress may be expected by the discovery of new species, both living and fossil; relating taxonomic data to investigations in other biological sciences; further understanding of evolutionary processes; development of new analytical techniques in mathematics, morphology and basic life processes; and also by verifying the facts and interpretations of past taxonomists as well as weeding out past errors of fact and theory. Basic research in taxonomy continues to have important effects in the applied sciences of medicine and agriculture.

**TAY**, the longest river in Scotland, has a catchment area of 2,400 sq.mi. (6,216 sq.km.) covering nearly all Perth and parts of Angus and Argyll. Its discharge is among the highest in the United Kingdom. The headwaters are at about 2,500 ft. (762 m.) on the north side of Ben Lui, east of Dalmally. Several small streams gather to form the Fillan Water, which, after passing through Lochs Dochart and Iubhair, is known as the River Dochart. The river then assumes a northeasterly direction for many miles among Highland hills of 2,000–4,000 ft.; it then enters the head of Loch Tay along with the River Lochay. On leaving Loch Tay, the largest lake in Perth, it receives the River Lyon, and about 5 mi. (8 km.) downstream of Aberfeldy it curves eastward to Logierait, where there enters, as a left-bank tributary, the flow from the great Garry-Tummel System, a main stream receiving the Rannoch-Tummel. The joint stream flows south-southeast to Dunkeld, receives the Highland River Bran on the right bank, and flows east-southeast through the gap between Birnam Hill and Newtyle Hill into fertile lowlands. It turns southwest at the great show at the Isla junction near Cargill and southeast once more near the junction with the Almond. After flowing through a gap

in the low hills continuing the line of the Sidlaws, on which the city of Perth stands, the river turns east to enter the Firth of Tay at the confluence with the Earn. From Newburgh in Fife, the firth runs northeast past Dundee to open out into the North Sea off Buddon Ness in Angus.

The firth broadens gently to 3 mi. upstream of Dundee, narrows to 1 mi. between Broughty Ferry and Tayport, and finally broadens to 3 mi. near its mouth, 120 mi. (193 km.) from the headwaters of Ben Lui. Dundee is accessible to shipping at all stages of the tide. Small vessels can reach Newburgh and even Perth, but navigation is impeded by shifting sandbanks. (A. T. A. L.)

**TAYLOR, (JAMES) BAYARD** (1825–1878), U.S. author known primarily for his lively travel narratives and for his translation into English of Goethe's *Faust*, was born in Chester County, Pa., Jan. 11, 1825. He was a restless student at Bolmar's Academy in West Chester, Pa., and the academy at Unionville, Pa., before he was apprenticed to a printer at the age of 17. In 1844 his first book, a volume of verse, *Ximena*, was published. He then made an arrangement with the *Saturday Evening Post* and the *United States Gazette* to finance a trip abroad in return for publication rights to letters describing his travels. His experiences in Europe resulted in the extremely popular *Views Afoot* (1846). In 1847 he settled in New York and began a lucrative career in journalism. *Eldorado* (1850) recounted his trials as a *Tribune* correspondent in the 1849 California gold rush. He continued his trips to remote parts of the world—to the Orient, to Africa, to Russia—and became renowned as something of a modern Marco Polo. In 1862 he became secretary of the U.S. legation at St. Petersburg, and in 1878, shortly before his death, became U.S. minister to Germany. He died on Dec. 19, 1878.

Some works of this later period were *The Poet's Journal* (1862); the novels *Hannah Thurston* (1863), *John Godfrey's Fortunes* (1864), and *The Story of Kennett* (1866); and the translation of *Faust* (1870–71), which remains his best-known work. Although greatly lauded in his day, Taylor was undistinguished as a novelist and poet, being at his best in his travel narratives and in an occasional richly textured poem, such as those in *Poems of the Orient* (1855). Collected editions of Taylor's poetical and dramatic works appeared in 1880.

**TAYLOR, BROOK** (1685–1731), English mathematician, noted for his contributions to the development of the calculus, was born at Edmonton in Middlesex on Aug. 18, 1685. He was educated at St. John's College, Cambridge, and studied mathematics under John Machin and John Keill. He obtained in 1708 a remarkable solution of the problem of the centre of oscillation, which, however, remained unpublished until May 1714, when his claim to priority was disputed by Johann (Jean) Bernoulli.

Taylor's *Methodus incrementorum directa et inversa* (1715) added a new branch to the higher mathematics, now designated the calculus of finite differences. Among other ingenious applications, he used it to determine the form of movement of a vibrating string, by him first successfully reduced to mechanical principles. The same work contained the celebrated formula known as Taylor's theorem, the importance of which remained unrecognized until 1772, when J. L. Lagrange realized its powers and termed it the basic principle of differential calculus.

In his essay on *Linear Perspective* (1715) Taylor set forth the basic principles of the art in an original and more general form than any of his predecessors; but the work suffered from the brevity and obscurity that affected most of his writings.

Taylor was elected a fellow of the Royal Society early in 1712, sat in the same year on the committee for adjudicating the claims of Newton and Leibniz, and acted as secretary to the society from 1714 to 1718. From 1715 his studies took a philosophical and religious bent. Taylor died on Dec. 29, 1731, at Somerset House, London, and was buried at St. Ann's, Soho. See also TAYLOR'S THEOREM.

**TAYLOR, DAVID WATSON** (1864–1940), U.S. marine architect, built the first ship-model testing establishment in the

United States, at the Washington (D.C.) navy yard, and formulated certain basic principles of ship design. Born in Louisa County, Va., March 4, 1864, he graduated from the U.S. Naval Academy in Annapolis, Md., and the Royal Naval College, Greenwich, Eng., with the highest grades made until then at those institutions.

Beginning in 1899, Taylor undertook the first studies to find what characteristics of a ship hull governed its water resistance. By a methodical series of extensive proportions, internationally known since 1910 as the Taylor Standard series, he determined the actual effect of changing those characteristics and thus made it possible to estimate in advance the resistance of a ship of given proportions. His *The Speed and Power of Ships* (1910), which sets forth this knowledge, is still an informative publication in its field.

From 1915 until 1921, Rear Admiral Taylor was responsible for the design and construction of surface and submarine vessels and of aircraft for the U.S. Navy, including the first plane to fly the Atlantic. He made many other contributions to aeronautics in 15 years of service on the National Advisory Committee for Aeronautics. (H. E. Ss.)

**TAYLOR, EDWARD** (c. 1645–1729), now generally considered the foremost poet in colonial America (his poems having remained in manuscript until 1939), was born in Leicestershire, Eng., in or near Coventry, probably of a dissenting family. Unwilling to subscribe to the required oath of conformity because of his staunch adherence to Congregational principles, he gave up schoolteaching, emigrated to New England, and was immediately admitted by Pres. Increase Mather as a sophomore at Harvard College. After his graduation in 1671, he was settled as minister in the frontier village of Westfield, Mass., where he remained until his death. Small in stature, he was remembered by his contemporaries for his intensity of nature and his personal charm. He married twice and became the father of 13 children, most of whom he outlived. His grandson Ezra Stiles, president of Yale College during the American Revolution, inherited most of his manuscripts and the greater part of his 200-vol. library.

By his express desire, Taylor's 400-page quarto manuscript "Poetical Works" was not published by his heirs. It came into the possession of Yale in 1883 by the gift of a descendant, and the best of Taylor's verse was published in 1939. The important poems fall into two broad divisions. "God's Determinations Touching His Elect" is an extended verse sequence thematically setting forth the grace and majesty of God as a drama of sin and redemption. The "Sacramental Meditations," about 200 in number, were written over a period of 44 years, from 1682 to 1725. Taylor described them as "Preparatory Meditations Before My Approach to the Lord's Supper."

The achievement of Taylor is his adroitness in fusing an ecstatic religious vision with earthly realities by means of homely diction and imagery drawn from the daily round of Puritan life. Central to all his poems is the typical metaphysical mode: the extravagant trope and the association of image and idea that is intended by its tension to draw poetic sparks.

*The Poetical Works of Edward Taylor* (1939), edited by T. H. Johnson, is a selection of poems, together with a biographical sketch, critical introduction, and notes. *The Poems of Edward Taylor* (1960), edited by Donald E. Stanford, is a comprehensive edition, including the complete text of the "Meditations."

(T. H. Jn.)

**TAYLOR, FREDERICK WINSLOW** (1856–1915), U.S. engineer who laid the foundation for scientific industrial management, was born March 20, 1856, at Germantown, Pa. In 1875 he was apprenticed as patternmaker and machinist in a small Philadelphia firm. In 1880 or 1881, while employed as a gang boss at the Midvale Steel Company, he became convinced that a standard day's work on any operation should be measured. This conviction led him to undertake a series of careful experiments resulting in important achievements in two fields: in mechanical engineering, the discovery with Maunsel White of a new method of tempering tool steel, permitting metal-cutting operations at high speed (1898); and in the field of management, perfection of that system

of shop management that later came to be known as scientific management. He introduced time-and-motion studies, as well as systems of incentive pay for labour. From 1893 to 1901, as consulting engineer in management for many industrial plants, Taylor forwarded the principles of scientific management. (See *MANAGEMENT SCIENCES*.) He died March 21, 1915, in Philadelphia.

Taylor's writings include *Notes on Belting* (1893); *The Adjustment of Wages to Efficiency* (1896); *Shop Management* (1903); *On the Art of Cutting Metals* (1906); and *The Principles of Scientific Management* (1911), reprinted in *Scientific Management* (1947).

See F. B. Copley, *Frederick W. Taylor, Father of Scientific Management* (1923); C. B. Thompson, *The Taylor System of Scientific Management* (1917).

**TAYLOR, JEREMY** (1613–1667), English clergyman and writer, represents the best of the religion and culture of the Anglican royalists during the period of the English Civil War, and his ornate prose is among the glories of the English language. He was baptized on Aug. 15, 1613, at Holy Trinity church, Cambridge, the son of Nathaniel Tay-

BY COURTESY OF THE WARDEN OF ALL SOULS COLLEGE, OXFORD PHOTO, THOMAS PHOTO

JEREMY TAYLOR: DETAIL OF PORTRAIT IN THE COLLECTION OF ALL SOULS COLLEGE

lor, a barber. He was educated at the Perse school, made a sizar of Gonville and Caius college in 1626, given a junior fellowship in 1633, and ordained in the same year. When he was deputizing for his friend Thomas Ridsen as lecturer at St. Paul's in 1633, his eloquence and good looks made a sensation, and brought him to the notice of Archbishop Laud, who was greatly impressed, but considered him too young for immediate preferment. Two years later, by a stretch of authority, he presented Taylor to a fellowship at All Souls college, Oxford. A friendship with Francis a Santa Clara (Christopher Davenport), a learned Franciscan, led to an often repeated and always vigorously repudiated accusation that Taylor had a leaning toward the

Church of Rome. In March 1638, William Juxon, bishop of London, presented him to the living of Uppingham, where he married Phoebe Langsdale on May 27. In the following November Taylor returned to Oxford to preach the annual Gunpowder plot sermon, the first of his published works. It is, in the main, a conventional attack on the recusants but some passages give promise of future greatness. In Nov. 1642 Taylor had left Uppingham and was with the king at Oxford, where he published his first important work, *Of the Sacred Order, and Offices of Episcopacy*. In it he assembles with persuasive skill most of the arguments then in circulation in favour of episcopacy, but adds little new. In 1643 he was made D.D. by royal decree and given the small living of Overstone, which he never visited. He next appears in Wales where he was taken prisoner with the royalist forces at Cardigan castle in 1645. On his release he joined the grammarian William Nicholson in setting up a school at Newton hall in Carmarthen shire, near Lord Carbery's seat at Golden Grove where he served as chaplain.

The next ten years were the happiest, and the most fruitful, of Taylor's life. His literary genius was at its height. *The Liberty of Prophesying* (1647) is a noble plea for religious liberty to be granted to all whose principles would not lead to the overthrow of the state or destroy the foundations of the Christian faith. After the Restoration, the breadth of toleration pleaded for in the book caused Taylor some embarrassment and he is said to have made an effort to suppress it, but there is little doubt that it expressed his real beliefs though he was not always able to practise them. *The Great Exemplar* (1649) consists of discourses, meditations and prayers on "the life and death of the ever blessed

Jesus Christ." It is the earliest of his devotional works and must have shown him the direction in which his gifts could best be exercised. *The Rule and Exercises of Holy Living* (1650) and *The Rule and Exercises of Holy Dying* (1651) so clearly supplement each other that they are usually regarded as one book. They were written to help members of the Church of England who were deprived of a regular ministry by the disturbances of the Civil War, but their wisdom and beauty have made them popular with all denominations. *Holy Living* contains encouragement to the life of prayer, general directions for godly living and prayers and meditations suited to both these subjects. With illustrations drawn from the classical moralists and a wide range of other reading as well as from Christian teaching, Taylor inculcates moderation, cheerfulness, contentment and reliance upon the divine goodness. By 1651 when he wrote *Holy Dying*, he had lost both his wife and his patroness, Lady Frances Carbery. He had been her spiritual director and close friend, and the oration which he delivered at her funeral is one of the finest in the English language. The first chapter of *Holy Dying* exhibits the full glory of Taylor's prose. The beauty of his language, the richness and variety of his fancy, match the nobility of his theme. Death is presented as an inevitable good for those who live and die as Christians. John Wesley owed much to these two books.

*Twenty-eight Sermons* (1651) and *Twenty-five Sermons* (1653) Preached at Golden Grove make up *Eniautos, a Course of Sermons for all the Sundays of the Year* (1653). They are full of beautiful cadences and delicately wrought images. *The Real Presence and Spiritual of Christ in the Blessed Sacrament* (1654) attacked the doctrine of transubstantiation. *Unum Necessarium* (1655), a study of repentance intended as prolegomena to a work of casuistry which he had long been meditating, contained a repudiation of Calvinistic doctrines of original sin and predestination which plunged him into controversy with high churchmen and Presbyterians alike. *The Golden Grove* (1655), a manual of instruction and prayers, contained also *Festival Hymns*, a collection of not very successful poems in irregular verse.

Taylor had by this time become the spiritual counselor of the diarist, John Evelyn, who helped him with gifts of money. After two short imprisonments for his religious principles (1655), he left Golden Grove and lived at Mandinam, an estate in Wales belonging to Joanna Bridges whom he had recently married. Later he moved to London and ministered to scattered congregations of Anglican royalists, frequently visiting great houses in the country. *A Discourse of Friendship* (1657), written at the request of Mrs. Katherine Philips ("the Matchless Orinda"), is his only secular work. *A Collection of Offices* (1658), intended as a substitute for the proscribed Book of Common Prayer, shows his wide acquaintance with eastern liturgies. Taylor had become intimate with Edward, 3rd Viscount Conway, who offered him a chaplaincy on his large estates in Ulster. He went there in June 1658 and for the next two years was mainly occupied with *Ductor Dubitanium—a Great Instrument for the Determination of Cases of Conscience* (1660), dedicated to Charles II. It is vast both in bulk and learning, a maze of illustration and digression, but remains of value for its profound scholarship and as the first complete work of casuistry in English.

Taylor's reputation for unorthodoxy militated against an English appointment, which he would have much preferred, and he was made bishop of Down and Connor (1660), to which was added, in 1661, the administration of the diocese of Dromore. He was also made a member of the Irish privy council and vice-chancellor of Trinity college, Dublin. There he was instrumental in reconstituting the university after the disorders of the Civil War. In his diocese he worked equally hard, but was not happy. The Scots who had colonized Ulster were followed over by Presbyterian ministers who were resolutely hostile to episcopacy. Thirty-six of them were in possession of church livings, and these Taylor deprived after they had refused all his advances. He filled their places with men from England or of English extraction. At his first visitation (1661) he preached on *The Minister's Duty in Life and Doctrine*, the best of his post-Restoration sermons, in a style less elaborate than his earlier work. At the request of his brother

bishops he wrote a *Dissuasive From Popery* (part i, 1664; part ii, 1667). Both are marred by overstatement and inaccurate quotation. *Chrisis Teleioteike* ("The Unction Which Perfecteth"; 1664) is the best study of confirmation to appear before the 19th century. Taylor died on Aug. 13, 1667, in Lisburn, of a fever caught while visiting a sick man. He was buried on Sept. 3 in Dromore cathedral, which he had himself rebuilt.

*The Whole Works of Jeremy Taylor* were edited, with a life, by Reginald Heber, 15 vol. (1822); there was a revised edition by C. Page Eden, 10 vol. (1847-54). *The Golden Grove, Selected Passages From the Sermons and Writings*, was edited by Logan Pearsall Smith, with a bibliography by R. Gathorne-Hardy (1930).

Humane, generous, impulsive, handsome, of great personal charm, Taylor was among the most lovable of men. His prose is filled with a joyous prodigality of beauty; in it he gave his genius full rein so that the sentences run on and on, gathering new beauty as they go, with complete indifference to orderliness or structure. In a learned age Taylor was one of the most learned and he poured all the wealth of his wide reading into his books, drawing perhaps most often upon the moralists of Greece and Rome. He was a close observer of nature and could describe with an inspired rapture the sheen on the breast of a dove, the groping tendrils of a vine or the petals of a newly opened rose. In spite of the vicissitudes of his life, his religious faith was of singular serenity and it is this which constitutes much of the charm of his devotional writings. He never threatens, but draws his reader to holiness by his own love of it. He has been accused of borrowing from other writers in his devotional books, but they are in fact entirely original. In controversy he was never at his best and in much of his other work he was apt to spoil his effects by overaccumulation of detail and superfluous argument.

As a theologian Taylor shared the Laudian love of beauty and order and respect for antiquity, but he was also influenced considerably by his contemporaries William Chillingworth and Henry More.

**BIBLIOGRAPHY.**—The earliest authority on Taylor's life is *A Funeral Sermon Preached at the Obsequies of . . . Jeremy Lord Bishop of Down by George Rust*, which can be relied on. Anthony à Wood's *Athenae Oxonienses* (1691) and *State Papers, Charles II, Domestic and Irish*, add details of interest. F. R. Bolton, *The Caroline Tradition of the Church of Ireland* (1958), supplies some details of Taylor's Irish period. E. Gosse, *Jeremy Taylor* (1903), has useful comments on Taylor as a writer but must be used with caution as to fact. Coleridge admired Taylor greatly and references to him are scattered throughout his prose works, especially in *Notes on the English Divines*, ed. by Derwent Coleridge (1853), and *Literary Remains*, vol. 3 (1838). See also C. J. Stranks, *The Life and Writings of Jeremy Taylor* (1952).

(C. J. Ss.)

**TAYLOR, JOHN** (1578-1653), English pamphleteer and journalist, commonly called "the Water-Poet," was born at Gloucester, Aug. 24, 1578. He was sent to a grammar school but became, as he said, "mired in Latin accident" and was apprenticed to a Thames waterman. He served in the Navy and saw action at Cadiz (1596) and Flores (1597). Returning to London, he worked as a waterman, held a semiofficial post at the Tower for some years and was an active member of the Watermen's Company. He increased his income and his fame by dedicating verses to noble patrons and by a series of extraordinary journeys, which he described entertainingly in oddly-titled pamphlets. With a companion as light-hearted as himself, he went from London to Queenborough, Kent, in a paper boat with two stockfish tied to canes for oars. He amused the court and the public, especially in his verbal battles with another eccentric traveler Thomas Coryate. *The Pennyles Pilgrimage . . . of John Taylor . . . on foot from London to Edenborough* (1618) describes a journey perhaps suggested by Ben Jonson's similar undertaking, though Taylor denied any suggestion of burlesque. He reached Braemar and, returning through Leith, met Jonson, who good-naturedly gave him 22 shillings to drink his health in England. He undertook a journey to Prague—where he was entertained by the queen of Bohemia (1620)—for a wager, as he did the travels described in *A Verry Merry, Wherry-Ferry-Voyage, or Yorke for my money* (1622) and *A New Discovery by Sea, With a Wherry From London to Salisbury* (1623). When the Civil War began, Taylor, who took a public house in Oxford (where

he stayed, in Oriel College, during the plague of 1625) wrote royalist pamphlets, but when the city surrendered (1645) he returned to London and kept "The Crown" (later "The Poet's Head") off Long Acre until his death in Dec. 1653.

Editions include: *All the Workes . . . beeing 63 in Number* (1630), reprinted, 3 pt. (1868-69); *Works . . . Not Included in the Folio Volume of 1630*, 5 pt. (1870-78); C. Hindley (ed.), *Works*, a selection (1872) and *Miscellanea Antiqua Anglicana*, vol. ii and iii (1873).

See R. B. Dow, "John Taylor" in *Harvard Summaries of Theses* (1931).

**TAYLOR, JOSEPH** (c. 1586-1652), English actor mentioned in the folio Shakespeare of 1623 as one of the 26 who took principal parts in all of those plays. He was with the Duke of York's Company in 1610 but involved himself in a lawsuit with John Heminge, by leaving it to join the Lady Elizabeth's in the next year. Taylor appeared in the actor list of the latter company in *The Honest Man's Fortune* (1613) and *The Coxcomb* (1613). From 1616 he was one of the Prince's Company and from 1619 was with the King's Men, where he remained until he retired, playing several of Burbage's parts, including Ferdinand in *The Duchess of Malfi* and Hamlet. There is a legend that he was trained by Shakespeare to play Hamlet. In many of Beaumont and Fletcher's plays he had a leading role, and he is one of the ten actors who signed the dedication of the first folio of those dramatists (1647). Taylor led the King's Men, with J. Lowin, after Heminge and H. Condell, and in 1630, after Heminge's death, obtained two shares in the Globe Theatre, and one in the Blackfriars. In 1639 he was appointed yeoman of the revels. He died at Richmond, where he was buried on Nov. 4, 1652.

**TAYLOR, MAXWELL DAVENPORT** (1901- ), U.S. Army officer, a pioneer in airborne warfare, was born at Keytesville, Mo., Aug. 26, 1901, and graduated from the United States Military Academy in 1922. Taylor assisted in the organization of the U.S. Army's first airborne division, the 82nd, early in World War II. At great personal risk, he passed through enemy lines 24 hours before the Allied invasion of Italy in 1943 to confer with Italian leaders in Rome concerning possible airborne seizure of Roman airfields. Later he led the 101st Airborne Division in the assaults in Normandy and the Netherlands, and his division gained wide fame for its defense of Bastogne during the "Battle of the Bulge" in 1944. As commanding general of the 8th Army in 1953 Taylor directed UN forces in Korea during the closing phases of the Korean War. He then served as Army chief of staff (1955-59) and three years later was appointed chairman of the joint chiefs of staff. In 1964 he became U.S. ambassador to the Republic of Vietnam, which was being given increasing military support by the U.S. He resigned this post in July 1965. (W. St.)

**TAYLOR, WILLIAM** (1821-1902), U.S. Methodist missionary, whose indefatigable zeal carried him all over the world in a missionary career that lasted nearly 50 years, was born in Rockbridge County, Va., on May 2, 1821, of Scotch-Irish and English parentage. On March 15, 1843, he was admitted on trial in the Baltimore Conference of the Methodist Episcopal Church and in 1847 was ordained elder. Taylor was sent to California in 1849 by the Missionary Society, arriving in San Francisco, via Cape Horn, when it was still a city of tents. Standing on a box or a whisky barrel in the plaza, he made his powerful voice heard by as many as 20,000 people and converted many.

Taylor's evangelistic tours, taken more or less independently of the church authorities, took him throughout the United States and Canada (1856-61), and to England (1862), Australia (1863), the West Indies (1864), India (1870-75), South America (1877-78, 1880, 1883-84), and South Africa (1866, 1884). On his first South American visit (1877-78) he organized a system of self-supporting schools on the west coast. Elected missionary bishop for Africa in 1884, he established a chain of missionary stations in the Congo and self-supporting missions in Liberia. His steadfast belief that "God had taken William Taylor into a peculiar partnership" filled him with self-confidence and courage and also made him impatient with official direction and supervision. For years he was a thorn in the flesh to bishops and board secretaries. In 1896 he was retired by the general conference, and he died on May 18, 1902.

Taylor wrote 14 or more books, including *Seven Years' Sinner Preaching in San Francisco* (1856); *Christian Adventures in South Africa* (1867); and *Story of My Life* (1896).

See Wade Crawford Barclay, *History of Methodist Missions*, vol. ii, pp. 179 ff. (1949-57); Oscar MacMillan Buck, "William Taylor" in *Dictionary of American Biography*, vol. xviii, pp. 345-346, (W. C. B.)

**TAYLOR, ZACHARY** (1784-1850), 12th president of the U.S., was born in Orange County, Virginia, Nov. 24, 1784. Within the year his father, Richard Taylor, an officer in the American Revolution, made a new home for his family in Kentucky, where he was appointed collector of the port of Louisville, then on the border where Spaniards and Indians were still a menace. In this environment Zachary Taylor spent his youth. He gained what little schooling he was to enjoy from Elisha Ayres, a New England tutor, who was employed by the elder Taylor. In 1806 young

THE BETTMANN ARCHIVE  
ZACHARY TAYLOR: DAGUERRETYPE  
PORTRAIT, 1849-50

Taylor volunteered during the difficulties caused by Aaron Burr's southwestern schemes and saw brief military service. Two years later, through the instrumentality of his relative James Madison and others, Taylor was given a commission by President Jefferson as first lieutenant in the 7th Infantry.

**Military Career.**—As captain and major he served through Harrison's Indian campaign and the War of 1812 in the Northwest Territory and at the close of the war temporarily left the Army because reduction to peacetime strength had lowered his rank. In 1816 President Madison reappointed him to his old rank, and there ensued 20 years of garrison life at various posts, varied in 1832 by an expedition against Black Hawk. At the outbreak of the Seminole War (1835) he was an infantry colonel in the Northwest; soon orders came for him to take his command to the Everglades. In this bewildering warfare he spent three years and was promoted to the rank of brigadier general by brevet for his service in the Battle of Lake Okeechobee. He was able to make little headway against the Indians and in 1840 asked to be relieved. He was assigned to duty in Louisiana and while there established a home in Baton Rouge and acquired a large plantation in Mississippi. In 1841 he was given command of the Second Department of the Western Division of the Army, with headquarters at Ft. Smith, Ark.

When Texas was acquired in 1845, Taylor was ordered by the War Department to take up a position along the southern border of Texas; by the spring of 1846 he had moved down to the mouth of the Rio Grande with a force of over 3,000 men and established Ft. Brown. A strong Mexican force was stationed at Matamoras, and soon there were border skirmishes that resulted in war. Even before war was declared on May 13, Taylor had defeated the Mexicans at Palo Alto (q.v.) and Resaca de la Palma on May 5 and 9. The news of these victories and of the occupation of Matamoras on May 18 was received with great appreciation throughout the country, and various persons, including Whig politicians and editors, began to look upon Taylor as a possible presidential candidate. After months of waiting for wagons and boats, Taylor moved to the head of navigation on the Rio Grande, established a depot at Camargo, and set out for Monterrey, which he captured on Sept. 21 after a hard-fought three-day battle. When President Polk disapproved the eight week's armistice granted by Taylor upon the surrender of Monterrey, and Secretary of War Marcy began to make suggestions as to the movements of his subordinates, Taylor became convinced that the administration was trying to discredit him for political purposes. His letter of Nov. 5 to Gen. E. P. Gaines criticizing Polk and Marcy found its way into the press, called forth a rebuke from the secretary of

war, and increased the friction between Taylor and Washington authorities. When his superior, Gen. Winfield Scott, preparing an expedition against Veracruz and Mexico City, ordered most of Taylor's seasoned troops to join him, Taylor was further incensed. Although instructed to concentrate his remaining troops at Monterrey and remain on the defensive, he crossed the mountains to Saltillo and on Feb. 22, 1847, engaged the army of Santa Anna in battle at Buena Vista (*q.v.*). Although outnumbered 4 to 1, the Americans, inspired by the leadership of "Old Rough and Ready" and aided by skilful artillery fire, won a brilliant victory and saved the north of Mexico. At home the feeling was general that Taylor had been treated unfairly by an administration that was jealous of his growing popularity.

**Political Career.**—Shrewd Whig politicians had become increasingly convinced of Taylor's potentialities as a candidate. Very early in the war, Thurlow Weed of New York began pushing him, and popular enthusiasm made his task easier. Taylor's correspondence was skilfully handled; he was reluctant, he maintained, and with truth, to be a seeker for the office; he had never voted and, though a Whig in sympathy, was not an avowed partisan. As a slaveholder he was certain to gain votes in the South, where there was a good deal of suspicion that Northern influences dominated the Whig managers. These advantages were sufficient to ensure success, and in the Whig convention, on the 4th ballot, Taylor won the nomination from Clay, Webster, and Scott. An opportune split in the Democratic Party ensured his victory, and on March 5, 1849, he was inaugurated.

Few presidents have entered office with less knowledge of what was expected of them. The new executive expected to be a non-partisan president, leaving to Congress all legislative matters and confining himself to executing the laws. With Colonel Bliss, his son-in-law, to phrase his thoughts, he, at first, was more or less influenced in his policies by Vice-President Fillmore, but it was not long before the superior astuteness of Senator Seward, Fillmore's rival in New York State, accomplished results. After the new president became convinced that it was his duty to build up the Whig Party by means of clever patronage, deserving Whigs began to come into their own.

With these preliminary lessons learned, Taylor found his most perplexing problem to be the status of the newly acquired territory. As a soldier he was eager to see stable government established, and for this purpose he authorized Congressman King of Georgia to go to California and urge an application for statehood. When Congress met in December 1849, the president had the pleasure of reporting that California was ready to become a state and that New Mexico would be ready soon. He recommended the admission of California and expressed the hope that the slave issue would not be injected into the situation. When southern representatives objected because California had prohibited slavery, he resented their protests. He declared himself willing to accept any law providing for admission and warned Southern leaders that he would take the field if necessary to carry out such a law and hang any who resisted. He was not in favour of conciliating those opposed to his policy and referred contemptuously to the Compromise of 1850 (*q.v.*) as the "Omnibus Bill." In other respects his administration was running into trouble; charges were made against his secretary of war, Crawford, to the effect that he had used his official position to pursue a claim successfully before the secretary of the treasury by which he benefited financially. This charge deeply mortified Taylor, who prided himself on scrupulous honesty, and he determined to reorganize his Cabinet. Then came the fatal July 4, 1850, when exposure to heat at the Washington Monument ceremonies and injudicious eating combined with worry brought on a serious intestinal disturbance that resulted in Taylor's death five days later. The doctors diagnosed his illness as cholera, but it seems to have been acute gastroenteritis. He was succeeded by his vice-president, Millard Fillmore (*q.v.*).

A combination of honesty, simplicity, determination, and common sense had brought Taylor successfully through a variety of difficult situations and by a strange turn of the wheel carried him to the White House. In 1810 Taylor had married Margaret Smith

(1788–1852), who bore him six children, three of whom survived him. One daughter, Sarah Knox Taylor, married a young subaltern, Jefferson Davis, in 1835, surviving the marriage but three months. His only son, Richard Taylor (1826–79), graduated from Yale in 1845 and, after a short service in his father's camp, became a sugar planter and politician in Louisiana. At the outbreak of the Civil War he entered the Confederate Army and eventually became a lieutenant general. His memoirs, *Destruction and Reconstruction* (1879), earned high praise from military historians.

**TAYLOR'S THEOREM**, the statement of an important mathematical formula discovered by Brook Taylor (*q.v.*) in 1712 and published three years later in his *Methodus incrementorum directa et inversa* (1715). The theorem later was recognized as a basic principle in differential calculus; the first rigorous proof was given by A. L. Cauchy (*q.v.*).

It may be written in the form of an infinite series:

$$f(x+h) = f(x) + hf'(x) + \frac{h^2}{2!}f''(x) + \dots \quad (1)$$

and under suitable conditions it makes possible the computation of the value of  $f(x+h)$  to any desired accuracy when the value of  $f(x)$  and its derivatives  $f'(x)$ ,  $f''(x)$ , . . . , for a particular fixed value  $x$  are known; e.g., with  $x = 1$ ,

$$\log_e (1+h) = 0 + h - \frac{h^2}{2} + \frac{h^3}{3} - \frac{h^4}{4} + \dots$$

Taylor's formula with remainder may be written as a finite sum:

$$f(x+h) = f(x) + hf'(x) + \dots + \frac{h^{(n-1)}}{(n-1)!}f^{(n-1)}(x) + R_n \quad (2)$$

where

$$R_n = \frac{h^n}{n!} f^{(n)}(x + \theta h)$$

and  $\theta$  is a fraction between 0 and 1. Several other formulas have been devised for  $R_n$ . Sometimes one of these may be used to check on the accuracy obtained by using a given number of terms of (1). Moreover, formula (2) is valid in some cases when formula (1) is not. The binomial series is a special case of Taylor's series (see BINOMIAL THEOREM).

(L. M. G.)

**TAYMYR NATIONAL OKRUG** (or DOLGANO-NENETSKIY NATIONAL OKRUG), created in 1930, forms the northern part of Krasnoyarskiy Kray, U.S.S.R. Area 339,498 sq.mi. (879,300 sq.km.); pop. (1965 est.) 36,000. The *okrug* occupies the hilly Taymyr Peninsula, the most northerly part of the Eurasian continent, which terminates in Cape Chelyuskin (77°45' N). From the Taymyr hills it extends southward across the north Siberian Lowland, drained chiefly by the Khatanga and its tributaries, across the steep, north-facing scarp of the central Siberian Plateau and includes the northern part of the plateau, known as the Putoran Mountains. In the west, the *okrug* includes the lowest part of the course of the Yenisey River. The northerly latitude brings an extremely severe climate, with prolonged, cold winters and brief, cool summers. Tundra conditions are found almost everywhere, with a scanty moss and lichen vegetation and areas of sphagnum bog. Only in the south does sparse, stunted forest appear. Included in the *okrug* is the Severnaya Zemlya (*q.v.*) Archipelago in the high Arctic.

The unfavourable conditions and remoteness (Dudinka, the administrative centre on the Yenisey, is 1,256 mi. [2,021 km.] from Krasnoyarsk) account for the sparse population (0.1 per sq.mi.). In Dudinka and two urban settlements there were 20,206 people in 1959, mostly Russians. The rural inhabitants are mostly seminomadic Nentsy (Samoyeds), who live by reindeer herding, fishing, and hunting. The chief wealth lies in the mining of the Putoran

Mountains, centred on Noril'sk, but that town is outside the *okrug's* jurisdiction. Dudinka, with 16,332 people in 1959, has rail connection to Noril'sk and serves as its outport. Ust'-Port, on the Yenisey, has a fish cannery. Dikson, at the mouth of the Yenisey (Yeniseyskiy) Gulf, and Nordvik, on the Khatanga (Khatangskiy) Gulf, where salt is obtained, are small ports on the northern sea route. (R. A. F.)

**TBILISI** (Tiflis), the capital town of the Georgian (Gruzinskaya) Soviet Socialist Republic, U.S.S.R., stands on the Kura River. Pop. (1966 est.) 823,000. It has an attractive appearance, laid out on hilly ground and cut through by the river, partly in a steep-sided and picturesque gorge. Its streets are tree lined, and there are many gardens and parks, including a botanical garden (1845). The modern architecture in general relies heavily on traditional Georgian and Armenian styles. Among architectural survivals of the town's long history are the Sion Cathedral, begun in the 5th century, although frequently rebuilt at later periods, and the Metekhi Palace of the Georgian kings. The many cultural and educational establishments, mainly on the right bank of the Kura, include the Georgian Academy of Sciences, a university, polytechnic and agricultural institutes, other higher educational institutes, more than 75 research foundations, a theatre of opera and ballet, and Russian and Georgian dramatic theatres. It is a centre of the film industry and of printing and publishing.

Besides the Georgian Military Highway across the Caucasus, Tbilisi has roads and railways to Sukhumi on the Black Sea, to Baku on the Caspian, and to Yerevan and Turkey. A branch railway runs to Telavi in the Alazani Valley. First in its wide range of industries is engineering, especially machine tools, agricultural equipment, and electrical products. Electric locomotives are made, and there are locomotive repair yards.

The textile industry is well developed and produces natural and artificial silk, cotton goods, and worsted. Plastics, leather goods and footwear, furniture and veneer, bricks, and chinaware are made, and brewing, wine making, and food processing (especially tea, margarine, and chocolate) are important. Power for industry is derived from the Ortchalskaya hydroelectric plant in the town itself and from the Zemo-Avchala and the two Samgora plants nearby.

The town is of ancient origin, founded in A.D. 458 (in some sources, 455), when the capital of the old Georgian kingdom was transferred there from Mtskheta. Its strategic importance in controlling the passage between western and eastern Transcaucasia gave the town a stormy history. It was captured and sacked on many occasions and knew many masters: Persians in the 6th century, the Byzantine Empire and the Arabs in the 7th. In 1122 King David II ("the Builder") of Georgia captured Tbilisi and made it his capital. In 1234 it fell to the Mongols, and in 1386 it was sacked by Timur. The Turks captured the town on several occasions, and in 1795 it was burned to the ground by the Persians. Its final capture was by the Russians in 1801, when it was a town of 20,000 inhabitants. The Russians constructed the Georgian Military Highway across the Caucasus to Tbilisi from Vladikavkaz (now Ordzhonikidze). (R. A. F.)

**TCHAIKOVSKY, PETR ILICH** (1840-1893), the most renowned of all Russian composers during the first half of the 20th century, was born at Votkinsk in the Vyatka Government on May 7 (new style; April 25, old style), 1840. He was greatly attached to his mother, and the tender feminine atmosphere of his early years was rudely broken when he was sent to school in St. Petersburg at the age of eight. In 1852 he entered the School of Jurisprudence, which he left in 1859 to join the Ministry of Justice as a senior clerk. In the meantime he had become an amateur musician and made some attempts at composition. In 1861 he began to study harmony, and the following year he entered the St. Petersburg Conservatory. At the end of his course he was appointed professor of harmony at the newly opened Moscow Conservatory. The composition of his First Symphony in 1866 produced acute nervous disorders that, together with hallucinations, were to affect him continuously. In 1868 he visited St. Petersburg, where he met Dargomyzhski, Balakirev, Rimski-Korsakov, and others. Surprisingly, he was received with more understand-

ing by these nationalists than by the conservatory-trained Moscow composers, and Balakirev in particular gave him invaluable help and advice. In 1869 his first opera, *The Voyevoda*, was produced in Moscow with mixed success, and later that year he composed the first version of his masterpiece, the *Romeo and Juliet Overture*, the subject of which had been suggested to him by Balakirev. The main compositions of the next few years were the First String Quartet (containing the well-known andante cantabile movement), the Second Symphony, and, in 1875, the First Piano Concerto and the Third Symphony. The concerto was written for his friend Nikolai Rubinstein, who, however, not only refused to play it but criticized it so mercilessly that Tchaikovsky rededicated it to Hans von Bülow. In 1876 he wrote *Francesca da Rimini* and his first ballet, *Swan Lake*, and his fourth opera, *Vakula the Smith*, was produced.

**Later Life and Works.**—The year 1877 was one of critical importance. It marked the beginning of his extraordinary association with his benefactress, Nadejda von Meck, a wealthy widow who, attracted both by Tchaikovsky's music and by his personality, provided him with financial independence for 13 years in the form of a generous annual allowance. By mutual agreement they never met, a fact that resulted in a voluminous intimate correspondence, throwing much light on Tchaikovsky's character. Another significant event was his disastrous marriage in July of the same year with Antonina Milyukova, a former music student. She had become infatuated with him in much the same way as Tatyana was infatuated with Eugene Onegin in the Pushkin opera on which Tchaikovsky was working at that time. Not being able to behave with Onegin's heartlessness, and hoping perhaps that marriage would conceal knowledge of his homosexual inclinations, Tchaikovsky married her on the understanding that, though physical love with a woman was denied to him, he would remain her friend. The resulting tension drove him to an attempt at suicide, and they were legally separated in October 1877.

Yet during this period he wrote some of his finest works. While working on *Eugene Onegin* he also wrote the Fourth Symphony, both completed abroad while he was recovering from his state of nervous depression. This rest did indeed help him forget the horrors of the past months, but both his compositions and his letters show that whatever happiness he was to enjoy during the remainder of his life would be increasingly modified by a tendency to melancholy and morbid introspection, which had always been ingrained in his nature. Soon after returning to Russia, Tchaikovsky abandoned his irksome conservatory duties and in 1881 declined the directorship of the conservatory. Between 1878 and 1881 he produced the *Violin Concerto*, the Second Piano Concerto, the *Italian Capriccio*, 1812 *Overture*, and the *Serenade for Strings*. Of his operas, the *Maid of Orleans* was a failure in 1881, but in 1884 *Onegin*, which had hitherto only achieved a *succès d'estime* in Moscow, enjoyed great popularity in St. Petersburg, largely due to the tsar's personal admiration for it. The third and best of his four orchestral suites also dates from 1884, and the following year he wrote his *Manfred* Symphony, again to a plan suggested by Balakirev. He began to spend more and more time traveling in Russia and abroad, and in 1888 he successfully undertook his first international tour as a conductor, visiting Leipzig, Berlin, Prague, Hamburg, Paris, and London. On his return to Russia he moved to Frolovskoye, where in 1888 he wrote his Fifth Symphony and the *Hamlet Overture*. After a second tour the following year he composed *The Sleeping Beauty* ballet, and in 1890 his second Pushkin opera, the *Queen of Spades*. An event embittering the remaining years of his life occurred in the autumn of 1890 when Madame von Meck discontinued her allowance under the false impression that she was near bankruptcy. Their epistolary friendship was thus brought to an end. In 1891 Tchaikovsky visited the United States, where he conducted concerts in New York, Baltimore, and Philadelphia. His two last works for the stage, the one-act opera *Iolantha* (1891) and the *Nutcracker* ballet (1892), were first performed together in December 1892 with only moderate success, although the famous ballet suite had already won favour. In 1892 Tchaikovsky moved to a house at Klin (later established as the Tchaikovsky Museum), where he wrote his Sixth Symphony

*Pathétique*; 1893), which he rightly believed to be a masterpiece. He lived only to hear the first performance, indifferently received; ten days later, on Nov. 6 (N.S.; Oct. 25, O.S.), 1893, he died suddenly in St. Petersburg from cholera caused by drinking unboiled water. Whether this action entailed an element of suicide—which he had often contemplated and once attempted—has never been established.

**Evaluation.**—Since Tchaikovsky's death no composer has suffered more from changes of fashion or from the extremes of over- and undervaluation. On the one hand he achieved an enormous popularity with a very wide audience (particularly adolescents), largely through his more emotional works; on the other, the almost hypnotic effect that he was able to induce led to serious questioning of his true musical quality. It seems probable that time will add to, rather than diminish, his stature, if only because performances, recordings, and publications have disclosed that there are fine works of Tchaikovsky still to be discovered. He is certainly the greatest master of the classical ballet, demonstrated by *Swan Lake* and the symphonically conceived *Sleeping Beauty*. The six symphonies may lack formal unity but all contain delightful music. The last three are deservedly famous, though to these should be added the neglected *Manfred* Symphony. On a somewhat lower plane the First Piano Concerto and the *Violin Concerto* nevertheless deserve a higher reputation than vehicles for virtuosity. Notable among his other orchestral works are the early *Romeo and Juliet Overture* and the exquisite *Serenade for Strings*. Although his operas contain many fine pages, Tchaikovsky was never a true operatic composer. *Eugene Onegin* is, however, a masterpiece, while the dramatically effective *Queen of Spades* has perhaps obscured the claims of *The Little Slippers*—his revised version of *Vakula the Smith*. The chamber and piano music is largely undistinguished, but his numerous songs include several fine examples.

Though unequal, his music shows a wealth of melodic inspiration and imagination, and a wonderful flair for orchestration. It also shows lapses of taste, partly redeemed, however, by his enormous technical efficiency. Though his work may be said to illustrate cosmopolitan tendencies of Russian music, its underlying sentiment and character are as distinctively Russian as that of the Russian nationalist composers. His success in bridging the gulf between the musician and the general public partly accounted for the exalted position he enjoyed toward the middle of the 20th century in the U.S.S.R.

**BIBLIOGRAPHY.**—G. Abraham, *Tchaikovsky* (1944); G. Abraham (ed.), *Tchaikovsky: a Symposium* (1946); H. Weinstock, *Tchaikovsky* (1943); P. I. Tchaikovsky, *Diaries*, Eng. trans. by V. Lakond (1945). (D. M. L.-J.)

**TCHEREPNIN, NIKOLAI NIKOLAEVICH** (1873–1945), Russian composer of ballets, songs, and piano music, was born in St. Petersburg on May 14 (new style; 2, old style), 1873. After studying law at the university, he entered the St. Petersburg Conservatory as Rimski-Korsakov's pupil for composition (1895–98). He became conductor of the Belyaev symphony concerts and of the imperial opera and from 1908 to 1914 conducted Diaghilev's opera and ballet productions in western Europe. From 1918 to 1921 he was director of the Tiflis Conservatory. He then settled in Paris, where he directed a Russian conservatory. He died at Issy-les-Moulineaux, near Paris, on June 26, 1945. Tcherpnin was a gifted but not a strikingly individual composer. The best of his ballet scores was the first, *Le Pavillon d'Armide* (1907). The most successful of the others were *Narcisse et Echo* (1911), *The Masque of the Red Death* (1916), and *Romance of a Mummy* (1925). Among his other works are symphonic poems, piano pieces (including *Esquisses sur les images d'un alphabet russe*), and songs.

Aleksandr Nikolaevich Tcherpnin (1899– ), pianist and composer of operas, ballets, orchestral works, chamber music, and piano works, son of the preceding, was born in St. Petersburg on Jan. 21 (N.S.; 9, O.S.), 1899. He studied first at Tiflis and later at the Paris Conservatoire. In 1918 he married the Chinese pianist Lee Hsien-ming. Between 1934 and 1937 he visited China and Japan and established a firm in Tokyo for the publication of works by Japanese and Chinese composers. He experimented with

a nine-note scale and with novel conceptions of rhythm. In 1948 Tcherpnin was on the faculty of the San Francisco Music and Art Institute. From 1949 to 1964 he taught piano and composition at DePaul University in Chicago. (G. Ab.)

**TCZEW**, a town and district capital in Gdansk (Danzig) *województwo* (province), Poland, on the left bank of the Vistula about 19 mi. (31 km.) above its mouth and 20 mi. (32 km.) SSE of Danzig. It is a railway junction for Warsaw, Danzig, Bydgoszcz, and Chojnice. Pop. (1960 est.) 33,696. It developed as an important river port on the main trade route to Danzig. After World War I it was a frontier town between Poland and the Free City of Danzig and handled the export trade in coal before the building of the port of Gdynia. It has a river shipyard, railway workshops, and a gasometer factory.

Tczew is mentioned in historical documents of the end of the 12th century. It was given to Poland in 1282 by the will and testament of the last duke of Danzig and Eastern Pomerania (Pomorze) but was occupied by the Teutonic Knights from 1308 until 1466. Seized by Prussia after the First Partition of Poland, in 1772, it was returned to Poland by the Treaty of Versailles in 1919. (T. K. W.)

**TEA**, a beverage made from the dried leaves of the tea plant, an evergreen shrub or small tree (*Camellia sinensis*) of the family Theaceae. Tea is consumed as either a hot or a cold beverage by about one-half of the world's population, yet it is second to coffee in commercial importance, largely because a significant portion of the world's tea crop is consumed in the growing regions. Of less importance are the medicinal properties of tea. Composed chemically of caffeine and tannin, tea is used as a stimulant and as an astringent, while the seeds of the tea plant are a source of a volatile oil.

The word "tea" comes from a Chinese ideogram pronounced "chah" in Cantonese and "tay" in the dialect of Amoy. As "chah," the word traveled to Japan, India, Persia, and Russia, but the English "tea" was derived from the "tay" form, which was brought by the Dutch to Europe by way of Java. In the known references to tea in English during the years 1650–59, the word appears in its earlier form of "tee" but was pronounced "tay." It was first spelled "tea" in 1660 but was pronounced "tay" until the mid-18th century.

**History.**—The origin of the use of tea as a beverage, though lost in antiquity, is rich in legend. Japanese mythology credits the origin of tea in China to the plight of Bodhidharma, the Buddhist saint, who is said to have remained seated before a wall in meditation for nine years. During one of his meditations the saint fell asleep, and, upon awakening, he was so chagrined that he cut off his eyelids to assure no recurrence of his sin. Cast to the ground, the severed eyelids took root and grew as the tea plant, whose leaves, when infused in hot water, produced a beverage that was capable of banishing sleep.

A Chinese legend places the introduction of tea as a beverage in the reign of the mythical emperor Shen Nung, about 2737 B.C.

THE BETTMANN ARCHIVE  
TEA PROCESSING IN CHINA: ENGRAVING FROM A 19TH-CENTURY ENGLISH BOOK

However, the earliest mention to which modern scholars give credence is found in the *Erh Ya*, an ancient Chinese dictionary, about 350 B.C. It is believed that tea cultivation began in the interior province of Szechwan in China, gradually extending down the Yangtze Valley to the seaboard provinces.

In the *Ch'a Ching*, a handbook of tea written by Lu Yu about A.D. 780, the product is described as a type of cake made from leaves that had been steamed, crushed, and molded. The cake was fired and toasted or shredded and then steeped in salted boiling water.

Tea cultivation was introduced into Japan, along with Chinese civilization, around the last decade of the 6th century. However, there is no record of successful tea cultivation in Japan until early in the 8th century, and not until the 13th century did tea become a popular Japanese beverage.

The Japanese variety of tea was introduced into Java in 1684 by Andreas Cleyer, a German naturalist and doctor of medicine. In 1827 a young Dutch tea taster, J. I. L. L. Jacobson, risked his life to penetrate China's forbidden tea gardens and bring back tea seeds and labourers in order to cultivate the tea plant in the Dutch East Indies. He is generally recognized as the founder of Indonesia's tea industry.

Tea was first mentioned in European literature in 1559 as *chai catai* (tea of China) in *Navigazioni e Viaggi* ("Voyages and Travels") by Gian Battista Ramusio, a noted Venetian author. The first reference to tea by an Englishman, in 1615, is credited to R. L. Wickham, who was in charge of the English East India Company's agency at Firando, Jap.

England was the greatest coffee-drinking country in the world when tea was first publicly sold at Garway's Coffee House in London in 1657. Advertised as "That Excellent and by all Physitians approved China drink," tea gained in popularity, and, within a few years, metal or leather trade coins, used in lieu of small change and known as tea and coffee tokens, were generally accepted as currency in London's 2,000 coffeehouses. The world's greatest tea monopoly, the English East India Company, which flourished from 1600 to 1858, played a major role in the introduction of China and India teas into England and colonial America and in popularizing the beverage. In an effort to perpetuate this monopoly, the British Parliament passed the Tea Act of 1773, which precipitated the Boston Tea Party and which was a contributory cause of the American Revolution. The colonists' resentment of the role played by tea in their bickerings with the mother country created an unfavourable image of the beverage, an image from which it never fully recovered. By mid-20th century, Englishmen were consuming about 5 times as many pounds of tea as coffee, while Americans were consuming about 25 times as many pounds of coffee as tea.

The use of tea as a beverage was well established in Holland by the mid-17th century, and the afternoon tea custom spread across the Atlantic to New Amsterdam (now New York City). With tea also came the teaboard, teapots, silver spoons, strainers, and other tea table items that were the pride of Dutch housewives. Milk was not used at first, but the socially correct ladies of New Amsterdam offered sugar and sometimes saffron and peach leaves as flavouring agents for tea. Their guests would either nibble a lump of sugar or stir powdered sugar into their tea; hence tea tables were provided with partitioned "bite and stir" boxes.

The custom of serving afternoon tea and cakes was originated by Anna, wife of the 7th duke of Bedford, around 1840. Since at that time people ate prodigious breakfasts and no other meal until dinner was served at 8 o'clock, the duchess instituted a new meal, with tea and cakes at 5 o'clock.

The founding of India's tea industry stems from the appointment of a committee by Gov. Gen. Lord William Henry Cavendish Bentinck, in 1834, to formulate a plan for tea cultivation. However, indigenous tea had already been discovered in northern India (upper Assam) by Maj. Robert Bruce and an Indian, Moneram Dewan, in 1823.

One of the most picturesque eras in maritime history was that of the clipper ships, which transported tea from China to England and North America. Its most celebrated chapter was perhaps

that of the Great Tea Race of 1866, which started at Foochow China, and ended 99 days later at London after covering 16,000 miles. Of the 11 competing clipper ships, "Taeping" was the winner at the London dock, and "Ariel" the winner at The Downs, ten minutes ahead of her rival.

**Botany.**—While the tea plant was originally designated by Linnaeus as *Thea sinensis*, it is now known botanically as *Camellia sinensis*, which emphasizes its close relationship to the cultivated

camellia, *C. japonica*. Many varieties of tea have been described and named, but there is no general agreement among botanists or horticulturists as to variety limits. A part of the difficulty is that early authors had wholly inadequate collections of reference material and that the tea plant in cultivation, like all cultivated plants, varies in character, depending on local conditions and on the special qualities for which various strains were selected and propagated.

BY COURTESY OF THE LIPTON TEA COMPANY

TEA STEM WITH FLOWERS

While the accepted scientific name stems from Linnaeus' description, the species was well known to earlier European botanical authors, for Linnaeus gives no less than ten references to earlier botanical literature.

The tea plant is an evergreen shrub, which in its natural state grows to a height of 15 to 30 ft., but the tea planter keeps it pruned down to a height of 3 to 5 ft. In its general appearance and the elliptic form of its two- to five-inch-long leaf, it resembles the myrtle. The five petaled blossoms are white, with yellow anthers, and suggest the wild rose; the fruit is a woody capsule containing three seeds. The plant grows well in the monsoon climate of the tropics, from sea level up to 6,000 ft., doing best in the higher altitudes; in more temperate zones, where there is danger of frost, it is grown at low elevations. The commercial tea belt of the world is largely confined to a ring of mountains around or near the Equator, within 42° N and 33° S.

**Diseases and Pests.**—The tea bush is subject to attack by a wide variety of pests and blights, but the greater number of them are comparatively harmless. Generally speaking, it is the neglected, undernourished, or otherwise weakened tea bushes that become prey to the attacks of blights. Among the leaf diseases that may be mentioned are: blister blight, gray, brown, and copper blight, bird's-eye spot, *Cercospora theae*, rim blight, sooty mold *Phoma theicola*, *Phaeosphaera theae*, and scabbed leaves.

Diseases that attack both leaf and stem include: blister blight, red rust, bacterial leaf and stem diseases, black rot, and horsehair blight. Stem diseases include: two varieties of branch canker, pink diseases, three varieties of dieback, *Massaria theicola*, stump rot, galls on plucked shoots, burrs, and callous outgrowths. Control of many of these diseases is effected by pruning and then burning the affected parts; spraying with Bordeaux or Burgundy mixture, or lime-sulfur solution; or more intensive cultivation.

Root diseases, which seldom ascend to the stem and branches, usually result in the death of the affected bushes. Certain diagnosis includes examination of the roots for threadlike fungus mycelium.

A serious insect menace is the helopeltis bug, the so-called tea mosquito, which thrives on the sap of young tea leaves. This pest is common in Java and parts of India.

Other enemies of tea are the leaf-rolling caterpillar of the tortrix moth, which enmeshes the tea leaves in its web, and the shot-hole borer *Xyleborus fornicatus*, a beetle that roams over the stems and branches, drilling holes that render the plants useless as tea producers. The latter pest is especially prevalent in Ceylon. Mites in chromatic profusion (red spider, orange mite, pink mite, yellow mite, etc.) attack tea leaves during a period of drought, turning them yellow and black, and ultimately causing them to fall off the bush. However, a good rain so stimulates growth that the bushes produce new vigorous shoots and usually survive

the attack. Certain species of termites and nematodes are pests locally.

In some cases insect attack actually produces higher quality teas; e.g., in India's premier hill districts of Darjeeling green fly attacks result in stunted leaves that provide some of the world's best teas.

**Cultivation.**—On large plantations, where tea is usually grown from seed in nursery beds, the young plants are transplanted to prepared tea fields when they are six to eight inches high, usually in six months' time. They are set out in rows, three to six feet apart. In two years, when they reach a height of four to six feet, they are cut down to less than a foot. By the end of the third year they are ready for plucking. Chinese, Japanese, and Formosan tea growers working mostly small family gardens do not set out nurseries but cultivate the shrub either by planting the seeds directly where they are to be grown or by layering; i.e., transplanting. Weeding, cultivation between the rows, and pruning continue regularly for 25 to 50 years, the average life of a tea bush. When in full bearing—about the 10th year—a plant yields as much as  $\frac{1}{2}$  lb. of leaf in its several flushes (growths of new shoots) during the season.

Tea leaves are plucked either by hand or with special shears. In the tropical areas of southern India, Ceylon, and Indonesia, harvest continues throughout the year, but in the subtropical regions of northern India and China and in Japan and Formosa, the harvests are seasonal. The flavour and quality of the tea leaves vary with the climate, soil, age of the leaf, time of harvest (even from season to season), and method of preparation.

**Manufacture.**—Teas may be divided into three classes: (1) fermented, or black tea; (2) unfermented, or green tea; and (3) semifermented, or oolong tea. These classes result from different processes applied to the same kind of leaf, or even to leaves from the same plant, though various regions generally specialize in one type.

Most stages of processing are generally common to the three types of tea. First, the fresh leaves are withered by exposure to the sun or by heating in trays until pliable (usually 18–24 hours). Next the leaves are rolled by hand or machine in order to break the leaf cells and liberate the juices and enzymes. This rolling process may last up to three hours. Finally, the leaves are completely dried either by further exposure to the sun, over fires, or in a current of hot air, usually for 30–40 minutes.

In making black tea, the leaves, after being rolled, are fermented in baskets or on glass shelves or cement floors under damp cloths, usually for  $\frac{1}{2}$  to 4 $\frac{1}{2}$  hours, followed by the usual drying process until the leaves are black and crisp. The process of fermentation, or oxidation, reduces the astringency of the leaf and changes its colour and flavour.

Green tea is made by steaming without fermentation in a perforated cylinder or boiler, thus retaining some of the green colour. The leaves are lightly rolled before drying.

Oolong teas, which have some of the characteristics of both black and green teas, are partially fermented before drying.

After drying, teas are graded by cutting, sifting, and sorting machines before being packaged. The principal grades are broken orange pekoe (terminal buds and the finest leaves); pekoe, pekoe souchong, and congou (successively coarser leaves); and pekoe dust (fine, broken tea).

Black teas are made in Communist China (the north China congou, or black leaf, from Hankow and the south China congou,

or red leaf, from Foochow), India, Ceylon, Java, Malawi, Kenya, Japan, and Formosa. Green teas are produced in Communist China, Japan, India, and Indonesia, while oolong teas are obtained from Formosa and Foochow.

**Production.**—**India.**—India, the world's largest producer of tea (mostly black teas), supplied about one-third of the total in the mid-1960s and also led the world in tea exports. Tonnage in both categories increased substantially after World War II. More than 60% of India's exports were shipped to the United Kingdom, while most of the balance went to the U.S.S.R., Egypt (U.A.R.), the U.S., the Republic of Ireland, and Canada.

The principal tea-growing districts of northern India are in the Assam Valley and Cachar, in the contiguous districts of Darjeeling and Jalpaiguri (more commonly known as the Duars), and in Terai in West Bengal. In southern India tea is grown in the elevated region overlooking the Malabar Coast in Kerala and in the Nilgiris hills. It is also cultivated on a much smaller scale in northwest India in the Kangra and Dehra Dun districts of Punjab.

Other than the teas sold under contract, those of northern India are sold at tea auctions in Calcutta or London, while those of southern India are auctioned in Cochin and London. Both Calcutta and Cochin are important shipping centres.

The Tea Board of India, established by the Tea Act of 1953, consists of a chairman and 38 members representing the central and state governments and all interests connected with the industry. It has extensive functions and responsibilities under the direction of the central government.

**Ceylon.**—Ceylon's production and exports of tea have also made rapid strides since World War II, holding second place to India. Though approximately 40% of Ceylon's exports go to the United Kingdom, large amounts are also exported to Australia, the U.S., South Africa, Egypt, Iraq, Canada, New Zealand, several minor European markets, and others.

The principal tea-growing districts of Ceylon are in the Central Province and Uva, but there are also extensive districts in the southwest, notably in the Kelani Valley. Known generally as Ceylons, these teas, though all black teas, are classified as high grown, medium grown, and low grown and by their district names. They are known specifically by their garden marks, of which there are more than 2,000. A tea land is said to produce high-grown tea if its mean elevation is 4,000 ft. or more above sea level; medium-grown tea between 2,000 and 4,000 ft.; and low-grown tea at elevations below 2,000 ft.

Colombo is the only local market and the principal shipping point. Weekly auctions are held there throughout the year, and the remainder of the crop is either sold by private contract or shipped to London for auction.

**Communist China.**—There are few tea plantations in China proper, but most of the tea is grown by farmers around their homes in the mountainous regions. For this reason a large portion of the tea-producing districts in eastern China remained intact despite eight years of Japanese occupation in the late 1930s and early 1940s. Although no statistics have ever been available as to acreage and production, authorities believe that China was the world's largest tea producer prior to 1936, but in the mid-1960s it was estimated that China placed third in both world production and export.

Prior to World War II, China's principal exports went to the U.S.S.R., followed by Africa, the United Kingdom, and the U.S. No official figures have been available since 1949, and importing countries' statistics exclude shipments of tea from Communist China to the U.S.S.R. and Eastern Europe. Shipments to these areas are judged to be sufficiently large to strip all other information of much of its significance. However, the United Kingdom, the Netherlands, Hong Kong, Egypt, and Australia have imported large quantities of Communist China's teas.

**Japan.**—Though Japan ranked fourth in world tea production in the mid-1960s, most of the tea was sold for domestic consumption. Green tea accounts for more than 80% of Japan's tea exports, with the largest portion going to North Africa, particularly to Algeria and Morocco. The United Kingdom and the U.S. also

CEYLON TEA CENTRE  
PICKING THE MOST TENDER LEAVES  
OF THE TEA PLANT WHICH YIELD THE  
BEST GRADES OF TEA

purchased some teas from Japan. The chief producing district is in the environs of Shizuoka, the centre of Japan's export tea trade. Almost the entire export is shipped through the port of Shimizu, eight miles away.

**Indonesia.**—Indonesia was the fourth largest producer of tea prior to the Japanese invasion in 1942, but during World War II and the postwar era tea production was reduced to a comparatively insignificant amount. By the mid-1960s production had begun to increase, and Indonesia stood in fifth place in world production. Until 1958, the Netherlands had been the largest importer of Indonesian tea, sometimes taking about 50% of the shipments. In that year the United Kingdom became the largest purchaser of Indonesian teas, followed by the Netherlands, Belgium, Australia, the U.S., and Germany. About 75 to 80% of the tea is grown in Java and the remainder in Sumatra. The principal tea-growing districts in Java are in the Bogor and Preanger areas in the western part of the island, but tea is grown almost throughout the island. In Sumatra, the chief tea-growing district is in the highlands south of Medan. Mainly black teas are exported.

Jakarta, on the northwest coast of Java, is the centre of the tea trade in Indonesia, its port being Tandjungpriok. Prior to World War II, the auction at Jakarta played a large part in the distribution of Indonesian teas, and these auctions, or tenders, were resumed in 1948. Tea also may be shipped to an outmarket against specific orders received from buyers, or it may be shipped to Antwerp or London for auction. Sumatra's tea export trade is centred in Medan and shipped from Belawan, 16 mi. away.

**Pakistan.**—Pakistan has made substantial gains as a tea producer since its establishment as an independent country in 1947. The United Kingdom, the largest customer for Pakistani tea, imports more than 75% of the total. The principal tea-growing region in Pakistan is in the district of Sylhet. Pakistani teas are generally black and are known as Sylhets and Chittagongs. Chittagong is the centre of the country's tea trade, and all teas are shipped through its port.

**Formosa.**—The tea industry of Formosa (Taiwan) has recovered well from the extensive damage it suffered during World War II. Its largest customers are the U.S., Morocco, the United Kingdom, the Netherlands, and Hong Kong. The tea districts are generally confined to the northern part of the island around T'ai-pei and Hsin-chu. T'ai-pei is the centre of Formosa's tea trade, and all teas are shipped from the port of Chi-lung, about 18 mi. away. About half of Formosa's teas are black; the remainder is either green or semifermented.

**Other Countries.**—Tea is grown in the U.S.S.R., principally in the Georgian S.S.R. and to some extent in the Azerbaijan S.S.R. Most of the tea plantations in this area of Transcaucasia are located on the southern slopes of the Adjar hills near the eastern shore of the Black Sea. This is the farthest north that tea is cultivated anywhere. There are no reliable statistics for tea production in the U.S.S.R. after 1945, but it is generally believed that production has increased tremendously since World War II. Considerable scientific attention is given to the cultivation and manufacture of tea, as well as mechanical picking. Besides consuming its own production, the U.S.S.R. imports tea from Communist China, India, and Ceylon.

Several African countries have become important as growers and exporters of tea. Outstanding among these are Kenya, Malawi, Uganda, and Tanzania (Tanganyika). The United Kingdom, the U.S., and Canada are among the leading importers of African teas.

A small quantity of tea is also produced commercially in Argentina and Brazil.

**Consumption.**—The people of Great Britain and Ireland are generally considered the world's greatest tea drinkers, consuming about ten pounds per person annually. Blends of India, Ceylon, Java, and China teas are the long-term favourites of the English and Irish people, and Indias and Ceylons are also drunk unblended to some extent. In the United Kingdom, the destination of about half of the world's tea exports, the afternoon tea is the most characteristic of British institutions.

FOX PHOTOS LTD

LONDON TEA BROKERS TASTING TEA

British people find little difficulty in satisfying their appetite for tea. It is served at tearooms, tea caravans, tea gardens, restaurants, and in railway cars, offices, and factories. Even the farmer's tea is brought to him while he is working in the fields. The right of English dock workers to an adequate tea was upheld in court following a strike that lasted several days.

In few countries is tea more popular than in Australia and New Zealand, where annual per capita consumption varies from seven to eight pounds. Blends of India, Ceylon, and Java teas are the most popular. In many homes and in most hotels, tea is served seven times a day, from before breakfast to immediately before retiring. Most large business establishments serve tea to their employees in the morning and afternoon. The tin "billy" can in which the bushman makes his tea is frequently referred to as a "Matilda" and is celebrated under this sobriquet in Australia's near-national song, entitled "Waltzing Matilda."

Canada is the foremost tea-drinking country of the Western Hemisphere, with an annual per capita consumption of almost three pounds. The demand is chiefly for Indias and Ceylons. The people of the Netherlands lead the nations of continental Europe as tea drinkers, with an annual per capita consumption of about two pounds.

Per capita consumption of tea in the United States is about  $\frac{1}{2}$  lb. annually. Consumption is heaviest in New England and the Middle Atlantic region, and otherwise among those people who have strong ties to countries where tea drinking prevails. Also some sections of the country are seasonal consumers, as the Southern states, where little hot tea is consumed in winter, but where there is liberal consumption of iced tea in summer. In the West and Midwest little tea is consumed at any time of the year. More than 90% of the tea consumed in the United States is composed of blends of Indias, Ceylons, and Indonesias, but Americans are generally indifferent to the cup quality of tea and have slight knowledge of the differences in types of tea. It is purchased by proprietary names owned by packers, retailers, or wholesalers.

Such merchandising innovations as iced tea, the tea bag, and instant tea have served to popularize tea in the U.S. and to americanize the beverage to some extent. Iced tea was first introduced—it would not be incorrect to say "invented"—at the St. Louis World's Fair in 1904. In the summer months iced tea competes favourably with leading soft drinks for public demand. Some form of tea bag or tea ball was known at the beginning of this century, and it replaced loose or bulk tea as the most popular form during the 1950s. Soluble, or instant, tea was first distributed widely around 1960. Its use has been primarily for iced tea, since it eliminated the need for boiling water in preparing the beverage.

As the most popular beverage in the U.S.S.R., tea is consumed at all meals and at all times of the day. It is usually served in

a glass rather than in a cup, and it is flavoured with lemon or jam rather than milk or cream.

The Chinese, originators of tea drinking, do not use teapots as a rule but simply infuse the tea with water much below the boiling point in the cups from which it is drunk, without milk, sugar, or lemon. Although no statistical data is obtainable, many authorities believe that the Chinese are the world's greatest tea consumers. Certainly in no other country except Japan does tea drinking appear to be more universal. Tea is drunk in China by people of all ages, in all classes, on all occasions, and at all times of day or night. It is served on receiving visits, making purchases, transacting business, and at all ceremonies. It is invariably offered on entering a Chinese house, and a covered, handleless cup, with freshly infused tea, is placed before each guest. The request to take more is generally construed as a polite hint that the interview or visit should end. In the cities, teahouses (*kwans*) flourish. They are the equivalent of the continental cafes and are the only convenient places of public resort. At a teahouse, the practice is to use two cups—a large one for brewing that will hold about  $\frac{1}{2}$  pt., and a thimble cup, smaller than a demitasse, from which the beverage is drunk.

Like the Chinese, the Japanese are great tea drinkers. They have a worshipful regard for it and refer to it as *O Cha*, meaning "Honorable Tea." It is the custom in the home, upon arising, to offer tea to one's ancestors by placing it before the altar and to offer it to one's parents before partaking oneself. Every woman of good family is schooled in the etiquette of the ancient tea ceremony as part of her classical education; at least three years of instruction and practice are considered necessary to acquire proficiency.

**Chemistry and Brewing of Tea.**—The principal chemical constituents of tea are caffeine, tannin, and essential oil. The first supplies the stimulating quality, which, because of its purity, is without harmful reaction; the second, the strength of body; and the third, the flavour and aroma, chief factors in determining cup value in a trade sense.

The ideal preparation of tea is one that extracts a maximum of caffeine and not an excessive amount of tannin. Such a preparation also conserves the aroma and flavour. From the chemist's point of view the two main essentials in tea brewing are fresh water, freshly boiled, and a three- to five-minute infusion. Since tea infuses more readily in soft water than in hard water, small, thick, full teas are required for soft water, while brisk, full, flavoury teas should be used with hard water. Generally speaking, a five-minute infusion is best for fully fermented teas, like those of India, Ceylon, or Indonesia.

**TEA CEREMONY**, a time-honoured institution in Japan, is rooted in the principle of Zen Buddhism and is founded upon the adoration of the beautiful in the daily routine of life, such as preparing a meal and tea, cleaning the house and garden, etc. The Japanese word for the ceremony, *cha-no-yu* (literally "hot water tea"), means an aesthetic way of entertaining guests, who, after they have been served a meal, are served thick, weak tea made of pulverized tea leaf stirred in hot water. Everything is done ac-

cording to the established rules of etiquette. The entertaining takes place in the tea room (*chaseki*), usually a small building constructed to suggest refined poverty, with great forethought given to the choice of material and the construction. The room is usually about nine feet square, or smaller. It contains an alcove for ornaments and a small sunken fireplace, which is used for heating the kettle during winter; in summer a brazier with a charcoal fire is used.

Each guest enters the room in humility by crawling through a small opening less than three feet square.

The founders of the tea ceremony emphasized the following four qualities: (1) harmony among guests and utensils; (2) respect, not only among the participants but also for the utensils; (3) cleanliness, derived from Shinto, the ancestral religion of Japan, which requires each participant, before entering the *chaseki*, to wash his hands and rinse his mouth as symbolic gestures of cleansing himself externally and internally; and finally, (4) tranquillity, which suggests the indescribable quality of mellowness which is given to the article by long and fond use.

**TEACH (THATCH), EDWARD** (d. 1718), English pirate, popularly known as **BLACKBEARD**, is believed to have been born at Bristol and to have gone to the West Indies during the War of the Spanish Succession (1701-13). He is first heard of as a pirate at the end of 1716. In 1717 he captured a large French merchantman, renamed her "Queen Anne's Revenge," and converted her into a warship of 40 guns. His outrages in the Caribbean Sea, and on the coasts of Carolina and Virginia, quickly earned him an infamous notoriety. In 1718 he made his base in an inlet in North Carolina, making an arrangement with the governor, Charles Eden, with whom he shared his prizes. The planters of that state finally requested help from the governor of Virginia, Alexander Spotswood, who sent two sloops under Lieut. Robert Maynard. On Nov. 22, 1718, Maynard boarded Teach's ship and, after a hard fight in the James River, shot the pirate dead.

See C. Johnson, *A General History of the Robberies and Murders of the Most Notorious Pirates* (1724); P. Gosse, *The Pirates' Who's Who* (1924).

(C. C. L.)

**TEACHER TRAINING** is generally concerned with preparation in subject matter and professional education, including psychology, methods, and practice teaching. This article covers principally teacher training for public elementary and secondary schools.

## HISTORY

France and Germany were beginning teacher education as early as the 17th century and have been influential in shaping patterns of training in other countries. With the secularization of schools in Germany, work in teacher education was greatly extended through the influence of Wilhelm von Humboldt (*q.v.*), who was named minister of education in 1809. He helped establish a planned educational program, set up regular standards and examinations for teachers, and encouraged the development of pedagogical seminars. In 1826 a year of trial teaching was established as a requirement of all candidates for teaching positions. In 1831 examinations in pedagogy as well as in the main subjects of the higher school course were designated as requirements for secondary school teachers.

Teacher education in the United States gained acceptance largely between 1820 and 1865. It was in the northeast that the normal school (the original name for teacher-training schools) took root. The common school with equal opportunity for people of all classes led inevitably to support of a normal school to train teachers; the widening range of ability of students attending school brought an emphasis on teaching methods. Thus because of widespread establishment of common schools, Samuel R. Hall opened his private normal school at Concord, Vt., in 1823. In 1839 the first of the public normal schools was established by the state of Massachusetts. Traditionally, however, the training of teachers

had been one of a purely liberal education, and the effort to professionalize teacher education started a continuing controversy. The Yale catalogue of 1829-30 required completion of a liberal education appropriate for all before the beginning of any professional training. However, Thomas Jefferson at the University of Virginia and George Ticknor at Harvard began experimenting in elective programs with subjects of utilitarian value for preprofessional work, and this influence helped the new normal schools to establish themselves. (See also NORMAL SCHOOL.)

The training of teachers dates, in England, from the beginning of the 19th century, when the National Society for Promoting the Education of the Poor in the Principles of the Church of England and its Nonconformist rival, the British and Foreign School society, first attacked the problem of elementary education on a national scale. Both societies adopted the "monitorial system," the principle of which was that picked older scholars should learn their lessons from the adult teacher in charge of the school and hand them on to the younger children. Some training of the instruments of this system was found to be necessary and training schools were accordingly set up to give it. One of these developed into the Borough Road training college, which is still in existence. About 1840 James Kay (afterward Sir James Kay-Shuttleworth), a far-seeing official to whom, more than to any other single man, the English educational system is due, began the movement which replaced the monitors by "pupil-teachers"; i.e., boys and girls who were regularly apprenticed for a period of five years from the age of 13 and both learned the art of teaching and continued their education under the head teacher of an elementary school. Kay's scheme also involved training colleges where the professional and academic education of at least the best pupil-teachers could be carried to a higher stage after their apprenticeship was completed. He himself founded the college which, as St. John's college, Battersea, London, was taken over by the National society and furnished a model widely imitated.

These early patterns of teacher education had their beginnings at a time when educational responsibility rested primarily with the church. When governments began to assume civil responsibility for establishing and maintaining schools, they also began to determine the preparation and qualification of teachers. As the percentage of children enrolled in school in the United States increased, and higher numbers continued into the secondary schools, standards of certification were raised and collegiate study was increasingly expected of elementary as well as secondary school teachers. The period from 1920 to 1930 has been described as that in which normal schools became teachers colleges in answer to this expectation. In England the first major development toward increasing educational opportunity came in 1918, but it was not until the Education Act of 1944 that it assumed significant proportions.

### IMPACT OF UNIVERSAL EDUCATION

In the 20th century, as the privileges of education were extended to more and more people throughout the world, the International Bureau of Education and later the United Nations Educational, Scientific and Cultural organization (UNESCO) actively promoted international exchange of information and the systematic gathering of educational data.

The predominant institution for the education of elementary teachers was a normal school following completion of the elementary school. Generally these institutions gave courses in both general and professional education. A few countries offered education for elementary teachers at the level of higher education, either through the university or through higher schools of education. Still other countries offered a combination of work beginning at the secondary level and extending into the higher education level.

The preparation of secondary school teachers was both academic and professional. Academic preparation was provided for in several ways: (1) through work at the regular universities; (2) through work at special institutions providing both academic and professional training; (3) by bringing in persons with special proficiency (engineers, for example, might teach mathematics, or

pharmacists, chemistry); (4) in special schools for music, physical education or art; (5) in countries with no higher educational institutions, teachers were sent abroad for training. Professional training was provided in a variety of ways.

Just as the beginnings of teacher education took place almost simultaneously in the various countries of western Europe, so following World War II there was a nearly universal review of the adequacy of education in an effort to extend opportunity to a larger number of the population in the various countries (see ILLITERACY: *Reduction of Illiteracy*; SECONDARY EDUCATION).

The United Nations Universal Declaration of Human Rights (adopted in 1948), which states that everyone has a right to education, made its influence felt in the recognition throughout the world of the need to extend compulsory education. The effect of these developments on teacher education was direct. Extension of teacher education was needed because of the extension of compulsory education, the increases in population of school age, and the extension of the years of schooling. In Costa Rica, for example, there were 3,500 students in secondary schools in 1948 and more than 30,000 in the 1960s. Enrollment in primary schools of Iraq was 90,000 in 1944 and 900,000 by the 1960s. Similar increases in primary and secondary school enrollments were experienced in country after country, with consequent attempts to expand teacher-training institutions and programs to keep pace.

The International Bureau of Education has, since 1931, conducted a yearly International Conference on Public Education after 1945 in co-operation with UNESCO. As early as 1935 pressures were felt on teacher education programs, and the 1935 conference was devoted to problems of the training of primary teachers. In the 1950s and 1960s the problems of primary teacher education and problems and issues in preparing secondary school teachers were the subjects of international conferences. The recommendations of these conferences reflected practice and also served as guideposts to ministries of education in formulating procedures in teacher education. These recommendations revealed common directions in systems of training and curricula which were generally considered to be desirable:

1. There appeared to be a definite trend in many countries to move away from the wide variety of teacher training institutions and toward the university or its equivalent for training both primary and secondary school teachers.
2. There was an attempt to extend the training of each group toward a longer period of general education for primary school teachers and toward more professional training for secondary school teachers.
3. There was recognition of the desirability of increasing contacts between primary school and secondary school trainees to facilitate continuity and transfer between schools.
4. There was general agreement that the qualifications for teaching should include social and psychological characteristics beyond those of intellectual ability alone.
5. There was recognition of the need for extensive psychological training for all teachers.
6. There was agreement that teacher training should include a strong practical aspect covering experience in various types of schools, extended probation under supervision and experience with extracurricular and community activities.
7. There was emphasis on training teachers to select and use a variety of methods appropriately.

**Courses and Requirements.**—The professional courses for secondary teacher training may be listed under three general headings: education, psychology, and practice teaching. Prevalent among education courses are those which deal with teaching methods and a general orientation to education. The psychology courses provide for general psychological orientation and child or adolescent psychology. Practice teaching is uniformly provided but differs in the length of time and type of work done by the student. In Austria a year of probationary service under the guidance of experienced teachers is provided. In the Federal Republic of Germany practice teaching includes two years of preparatory service following academic studies with two four-week periods of practical work in a school during vacations.

The subjects taught in primary teacher training establishments reflect the following persistent requirements in the area of general education: mother tongue, a second language, history, mathematics, sciences, and geography. Professional subjects closely approximate the course offerings indicated in the requirements for preparation of secondary teachers. More specialized provision is made for the study of child psychology, together with more emphasis on methods. Persistent offerings in special subjects include physical culture, drawing, penmanship, music, handwork, domestic economy, agriculture and rural studies, health, and arts and crafts. These subjects reflect a trend to train teachers in areas that will enable them to contribute to national needs in agriculture, health, and domestic patterns. Furthermore, they indicate that primary education universally deals with a wider variety of cultural emphases than reading and writing alone, and that these subjects are of sufficient significance for recognition in the curricula of teacher education.

A comparative study of teacher training for primary schools in the U.S.S.R. and the U.S. revealed many similarities between the four-year course in pedagogical schools for the training of primary school teachers in the U.S.S.R. (1955-56) and the four-year course of the State Teachers College at Oneonta, N.Y. (now State University of New York College at Oneonta). In the U.S.S.R. the teachers took Russian language and methods of teaching, literature, mathematics and methods of teaching, physics, chemistry and mineralogy, natural science and methods of teaching, geography and methods of teaching, history and methods of teaching, history of the Communist party, psychology, pedagogy, history of pedagogy, logic, school hygiene, penmanship and methods of teaching, drawing and methods of teaching, singing and methods of teaching, physical education and methods of teaching, practical work in shop and agriculture, observation and practice teaching, and electives. In Oneonta the course included art, child development, written composition and speech, mathematics, music, physical education, introductory science, biology, history, the child and his curriculum, health education, industrial and practical arts, literature, geography, U.S. history and government, practice in elementary school teaching, seminar in elementary education, sociology, and electives.

The fundamental difference in the two programs was in the emphasis which the Soviet program gave to teaching methods in direct relation to subjects, while the Oneonta course gave separate consideration to the child and his curriculum, which was a two-year integrated methods course.

**Standards.**—The quality of teacher training has been of much concern. In England the area training organizations (A.T.O.) have been given responsibility for all types of students in training. The A.T.O. links the training colleges in a given area with a university institute of education, which exercises supervision over, and approves courses and conducts examinations for, the colleges. The local education authorities also are represented in the A.T.O.

The National Council for the Accreditation of Teacher Education in the United States has worked on such problems as setting up criteria for selection of candidates in teacher education, the balance between general and professional courses, adequate supervision of practical teaching, selection of laboratory experiences and the encouragement of research to determine the effectiveness of applied criteria.

A threat to the quality of training has been the shortage of teachers. At the same time that attention was being given to improving quality and extending time for programs of teacher training in a majority of countries, those same countries were forced to set up emergency training measures. Many countries provided increased living allowances for students in training, in order to encourage more people to enter the profession. Others temporarily shortened the training periods. Appointments were made with required part-time study to bring the emergency teacher up to standards. Some academic university scholars, critical of the emphases on teaching methods courses, urged more attention be paid to competency in subject matter in setting standards for teaching appointments.

**Supplementary Education and Training.**—As in other pro-

fessions, newer methods and new developments in the fields of knowledge necessitate further education for teachers with experience. In many countries seminars or institutes are conducted by the government. The content reflects the major concern of the governmental agency. For example, Czechoslovakia, Belorussia, and the U.S.S.R. required a summer training course for teachers to prepare for greater emphasis on practical and polytechnic training in the secondary curriculum. Materials centres either in a central place or in a bookmobile have been used to bring new ideas to teachers on the job.

In the United States local school systems frequently sponsor in-service training courses, and the universities conduct extensive summer programs for teachers. The National Science Foundation set up training programs for teachers and equipped traveling science laboratories to serve the double purpose of educating children and teachers in contemporary science. The continental classroom television program was another effort to bring current information in specialized fields to teachers. The National Defense Education Act, and amendments in the 1960s, provided for loans and fellowships for students planning to teach in various fields, and for teacher-training institutes and for aid to further education for teachers.

Even before education became a civil responsibility, members of the profession met to share ways of improving their work. They have cooperated with government and institutions of higher learning in modern efforts. They work with the A.T.O. in England, and they have developed significant and influential plans for educational improvement in Ireland, Scotland, Australia, and Canada. In Ontario, for example, they have conducted summer workshops for teachers and developed a permanent training centre. The National Education Association of the United States with its various affiliates has conducted continuous research for the improvement of the profession. (See also EDUCATION, SOCIETIES OF.)

Other significant developments in further education include research centres. In Brazil, for example, the Brazilian Centre of Educational Research was established in 1955. "The purposes of these centres are: (1) to study cultural and educational conditions and trends in the development of each region and of Brazilian society as a whole, with a view to formulating, by degrees, a national education policy; (2) to draw up plans and make recommendations and suggestions for the reform of Brazilian education in every region and at all levels; (3) to prepare reference works, textbooks and educational materials and to conduct special studies on school administration, curricula, educational psychology and philosophy, the training of teachers and any other matters connected with the improvement of teacher training; (4) to arrange training and refresher courses for school administrators, those responsible for educational guidance, educationists and primary teachers in teacher training and primary schools." ("Education in Brazil," *Education Abstracts*, vol. x, no. 9, p. 6, UNESCO, Paris, Nov. 1958.)

Newer communication media have also influenced teacher training. The use of video tape made it possible for a teacher to teach a group of students, then view his own work immediately, and thus perhaps improve his teaching. Tape recorders have been used the same way in addition to their use in speech and foreign languages.

The 20th century has seen the wide use of international exchange in the training of teachers. The technical assistance programs of UNESCO, the International Cooperation administration and the Fulbright scholarship programs in the United States, the British council, the Ford and Rockefeller foundations, the American Friends Service committee and the Southeast Asian Board of Scholarships and Exchange of Professors have made international exchange significant in the training of teachers throughout the world (see also STUDENT AID). These exchanges helped to establish certain common directions in teacher education, but they emphasized the fact that teacher education must be rooted in the culture and expectation of the particular country in which functions.

**TEACHING METHODS** are systematic procedures for the organization and presentation of instructional materials and activities. Confusion arises in the use of the term because "method" is used to designate comprehensive, systematic approaches, as, for example, "the Montessori method" (see MONTESSORI SYSTEM), and also to identify subsidiary techniques or devices that may be used in various systems, as "the textbook method," "the lecture method," and the "audio-visual method" (see AUDIO-VISUAL EDUCATION).

The development of teaching methods in various systems of pre-elementary, elementary, and secondary education is traced in EDUCATION, HISTORY OF. See also PRE-ELEMENTARY EDUCATION; ELEMENTARY EDUCATION; SECONDARY EDUCATION. For general discussion of psychological factors, learning theories, and methods in various subject areas, see EDUCATIONAL PSYCHOLOGY. See also LEARNING; PROGRAMMED LEARNING; EXAMINATIONS; EDUCATION, PHILOSOPHY OF. See further EDUCATION (ARTICLES ON).

**TEAK** is one of the most valuable world timbers. Known from ancient times—the Sanskrit name is *saka*—teak has been widely used in India for more than 2,000 years. The generic name *Tectona* is from the Malayan word *tekku*. Teak is a large deciduous tree of the verbena family (Verbenaceae), with a straight but often buttressed stem, a spreading crown and four-sided branchlets with large quadrangular pith.

The leaves are opposite, or sometimes whorled in very young specimens, 1 to 2 ft. (0.3 to 0.6 m.) long and 6 to 12 in. (15 to 30 cm.) wide. On sucker shoots and seedlings the leaves are much larger, often from two to three feet long. In shape they somewhat resemble those of the tobacco plant, but their substance is hard and the surface rough. Small white flowers, very numerous, in

large, erect, cross-branched panicles, terminate the branches. The fruit is a drupe, two-thirds of an inch in diameter. The bark of the stem is about one-half an inch thick, gray or brownish-gray, the sapwood white; the unseasoned heartwood has a pleasant and strong aromatic fragrance and a beautiful golden-yellow colour, which on seasoning soon darkens into brown, mottled with darker streaks. The timber retains its aromatic fragrance to a great age.

Teak thrives best in districts with a mean annual rainfall of more than 50 in. (1,270 mm.) and a mean annual temperature between 75° and 81° F (24° to 27° C). It is native to India, Burma and Thailand; its natural northern limit of growth in these areas is about the 25th parallel, although plantations have been established as far north as the

32nd parallel in the Punjab. The tree is not found near the coast; the most valuable forests are on low hills up to 3,000 ft. (914 m). Stands are also found in the Philippines, in Java and elsewhere in the Malay archipelago, although there is no record of its being native in those places. Teak grows on a great variety of soils, but there is one indispensable condition—perfect drainage or a dry subsoil. On level ground, with deep alluvial soil, teak does not always form regularly shaped stems, probably because the subsoil drainage is imperfect.

During the dry season the tree is leafless; in hot localities the leaves fall in January, but in moist places the tree remains green until March. At the end of the dry season, when the first monsoon rains fall, the new foliage emerges.

The principal value of teak timber for use in warm countries is its extraordinary durability. In India and in Burma beams of the wood in good preservation are often found in buildings several centuries old, and instances are known of teak beams having lasted more than 1,000 years. In one of the oldest buildings among the ruins of the old city of Vijayanagar, on the banks of the Tungabhadra in southern India, the superstructure is supported by planks of teakwood 1½ in. thick. These planks, examined in 1881, had been in the building for 500 years and were still in a good state of preservation and showed the peculiar structure of teak timber in a very marked manner. In the wall of a palace of the Persian kings near Baghdad, which was pillaged in the 7th century (two archaeologists in 1811 found pieces of Indian teak which were perfectly sound. In the old cave temples of Salsette and elsewhere in western India, pieces of teak which must have been more than 2,000 years old have been found in good preservation. The timber is practically imperishable under cover.

Teak is used for shipbuilding, fine furniture, door and window frames, wharves, bridges, cooling tower louvers, flooring, paneling, railway cars and venetian blinds. An important property of teak which affects utilization is its extremely good dimensional stability. It is of medium weight (45 lb. per cubic foot), strong and of average hardness. Termites eat the sapwood but rarely attack the heartwood; it is not, however, completely resistant to marine borers. Although the tree flowers freely, few seeds are produced as many of the flowers are sterile. Spread by self-sown seed is impeded by the forest fires of the dry season, which in India generally occur in March and April, after the seeds have ripened and have partly fallen. Although germination is slow in its youth the tree grows with extreme rapidity. Two-year-old seedlings on good soil are five to ten feet high, and instances of more rapid growth are not uncommon. In Burmese plantations teak trees on good soil have attained an average height of 60 ft. in 15 years, with a girth, breast high, of 19 in. In these plantations it is estimated that the tree under favourable circumstances will attain a diameter of 24 in. (girth 6 ft.) at the age of 30. Normal exploitable girth limits are 7 ft. 6 in. for good forests, and 6 ft. 6 in. for poor teak forests. In the natural forests of Burma and India, teak timber with a diameter of 24 in. is never less than 100 and often more than 200 years old. Mature trees are generally not more than 100 to 150 ft. high.

Although the largest volume of teakwood produced is used in India and Burma, Ceylon and the east, much of the best quality is exported. Burma produces most of the world's teak supply. India, Thailand, Java and Ceylon rank next in production.

Burma teak comes mainly from the Pegu Yomas and Chindwin drainage areas, and is floated down the Sittang and Irrawaddy rivers to Rangoon. The most important teak forests in India are found in Madhya Pradesh, Mysore, Madras, Coorg, Bombay and Kerala. Practically all Indian teak is utilized within the country and the supply falls short of actual requirements. Thailand teak is shipped from Bangkok mainly to European markets. Teak has been cropped in Central America and elsewhere in the new world but it has never been commercially successful.

See United Nations Food and Agricultural Organization, *Country Reports on Teak* (1956).

**TEASDALE, SARA** (1884-1933), U.S. poet whose work is personal and confessional in nature, is noted for its classical simplicity and lyric intensity. She was born in St. Louis, Mo., and

FOOD AND AGRICULTURE ORGANIZATION OF THE UNITED NATIONS  
AGED TEAK LOG SECTIONED TO SHOW ITS SEASONED DARK HEARTWOOD

Aug. 8, 1884, and was privately educated there. Upon her marriage in 1914 she moved to New York, where she continued to make her home after being divorced in 1929. She died in New York City on Jan. 29, 1933.

Encouraged by her family, Sara Teasdale began writing at an early age and published her first book, *Sonnets to Duse and Other Poems*, in 1907. From the beginning her work was well received; with *Rivers to the Sea* (1915) she was established as a popular poet; for *Love Songs* (1917) she won the Pulitzer Prize for poetry in 1918. These early poems, some of which became for a time standard anthology pieces, typically express a variation of the theme of feminine love, employ the simplest of lyric forms, and give the impression of spontaneous and liquid movement. Gradually, however, her poetry developed gravity and dignity, and her later books—especially *Dark of the Moon* (1926)—include poems that display great purity of form and technical brilliance. Her work is narrow in range and written in a distinctly minor key, but on occasion it rises to excellence.

Her *Collected Poems* appeared in 1937.

**TEBESSA** (the Roman *THEVESTÉ*), a town of Algeria, lies on a plateau 146 mi. (235 km.) S of Bône and 12 mi. (19 km.) W of the Tunisian frontier. Pop. (1960) 26,622. The hub of the town is Kasbah square and there is a modern church built from the ancient ruins.

The central feature of the triangular-shaped town is the walled Byzantine citadel, a square with 12 towers and 4 gateways. Solomon's gate, on the east, was named after the Byzantine general who built the ramparts in 530; and on the north is the splendid Roman quadrifrontal arch of Caracalla (214), each side of which is flanked by a pair of monolithic columns. The temple of Minerva, built in 211, is now a museum containing remarkable mosaics and sculptured oil lamps. The most beautiful historic building is the Christian basilica, 1 mi. N from the town centre and restored in the 1930s. It has traces of three successive constructions: the subterranean church and its catacombs (1st century); the first basilica (315–350), one of the strongholds of the Donatist heresy; and the upper basilica (after 350). Together with gardens and the remains of a 6th-century Byzantine military establishment, it makes one of the loveliest sights of Algeria. Outside Solomon's gate are the ruins of a Roman amphitheatre, and to the south of the town hot baths were uncovered.

A prehistoric site, Tebessa was an outpost of Carthage in the 7th century B.C. and in 146 B.C., a Roman garrison. At its height in A.D. 200, it declined in the 5th century under Vandal dominion and in the 6th century was occupied by Byzantines and later by Berbers. With the Arab invasion of the 7th century it disappeared from history. The Turks stationed a small garrison of janizaries there in the 16th century, but after French rule began in 1840 Tebessa was developed as the easternmost of the Algerian gateways to the south.

Tebessa is linked by rail to Bône and is also a road junction, and its airport ( $\frac{1}{2}$  mi. away) is served by French airways. In addition to working the important phosphate mines of Kouif (north-east of Tebessa and linked by rail), the people live by trade, especially in sheep, esparto and grain, and there is a thriving handicraft production of carpets. (R. Gu.)

**TEBU** (TIBBU, TUBU), a Muslim Negro-Berber people of the eastern and central Sahara (*q.v.*) who were estimated to number about 35,000 in the 1960s. Living either as nomadic herdsmen or as farmers (*e.g.*, near oases), they have two major tribal divisions: the Daza and the Teda. Dates are a staple; a variety of grains, legumes, and root crops are cultivated; cattle, goats, donkeys, camels, and sheep are kept; and caravan trade is an important factor in the economy. Sedentary Tebu villagers typically have palm-thatched, rectangular mud houses (Daza) or cylindrical huts of mud or stone with conical thatch (Teda). They are patrilineal, pay bridewealth (*q.v.*; usually livestock), and first-cousin marriage is tabu; polygyny is not uncommon. Commoners are distinguished from nobles, and the Teda tribe have a so-called sultan, but real power typically rests with local headmen who inherit their offices. See also BORKU; CHAD, REPUBLIC OF; FRENCH EQUATORIAL AFRICA; NIGER, REPUBLIC OF THE.

Völkerk.*, vol. 11 (1956); G. P. Murdock, *Africa: Its Peoples and Their Culture History* (1959); L. C. Briggs, *Tribes of the Sahara* (1960).

**TECHNETIUM**, element 43, was the first example of the creation of a hitherto unknown element by artificial means. The name, from the Greek word meaning artificial, commemorates this fact and has been accepted by the International Union of Chemistry. It is the homologue of manganese (25) and rhenium (75) in the periodic system. Formerly known as masurium, it follows molybdenum (42) and precedes ruthenium (44). The chemical symbol is Tc, and the atomic weight (mass number) of its best-known isotope is given as 99.

This element has been extensively sought in natural ores, notably by I. Noddack and W. Noddack, who in 1925 claimed to have detected its X-ray spectrum in the same series of experiments that led to the discovery of rhenium. However, the findings of the Noddacks were not confirmed by other experimenters. It is now known that its natural existence is most improbable because it would contradict well-established rules of nuclear stability. However the possibility of the existence on the earth of extremely small amounts of some radioactive isotope of technetium, possibly Tc<sup>98</sup>, is not ruled out.

In 1937 E. Segrè and C. Perrier found several radioactive isotopes of element 43 in molybdenum targets that had been bombarded with deuterons in the cyclotron. Using the methods of radiochemistry, they gave positive evidence that some of the radioactivity was produced by element 43. At the same time they established several chemical properties of the new element.

Technetium can be produced by several types of nuclear bombardment, such as neutrons on molybdenum or deuterons on molybdenum, and is also a product of the fission of uranium (O. Hahn and F. Strassmann, E. Segrè and C. S. Wu). The latter nuclear reaction promised to supply the largest amounts of the element. If it existed in ores, its geochemistry would probably be similar to that of rhenium.

The element is metallic in its properties; it is isomorphous with rhenium; and Tc<sup>99</sup> has a density of 11.49 gr./cm.<sup>3</sup> Metallic technetium becomes a superconductor at 11.2° K. In the course of a chemical analysis technetium would separate in the second group (sulfides insoluble in acid solution) and would usually appear with rhenium, although it can be separated from this element by a distillation at 180° C. in a current of hydrogen chloride. Its separation from molybdenum, which is often of practical importance, can be obtained by precipitating the molybdenum from an acetic acid solution with 8-hydroxyquinoline. Technetium stays in solution.

Among the technetium compounds are the oxides TcO<sub>2</sub>, Tc<sub>2</sub>O<sub>7</sub>, the sulfide Tc<sub>2</sub>S<sub>7</sub> and the important ion TcO<sub>4</sub> which gives pertechnetates similar to permanganates and perhenates.

Not less than 13 isotopes of technetium are known ranging in mass number from 92 to 105. They are all radioactive, some emitting electrons, some decaying by orbital electron capture and some undergoing isomeric transitions. Following these isomeric transitions, the characteristic X-ray emission of technetium is observed; this provided an early opportunity for the spectroscopic observation of the K X-ray lines of this element before macroscopic amounts of it were available.

Beginning in 1944, substantial progress in the study of technetium was made in the laboratories of the atomic energy agencies of several countries. Since Tc<sup>99</sup> has a beta-decay period of about 200,000 years, it was possible to isolate many grams of it. This isotope is obtained either as a fission product or by neutron capture of molybdenum followed by a beta decay.

If the technetium formed in nuclear reactors in existence in the mid-1960s were extracted, there would be an annual production of several hundreds of kilograms, quite comparable to the annual production of some of the rarer natural elements. Thus the possibility of practical applications for this element is not excluded. In this connection it is interesting to note that it has been reported that technetium compounds and alloys are very effective in the prevention of corrosion.

The availability of relatively large amounts of technetium permitted study of it through the ordinary methods of chemistry and physics, without taking advantage of its radioactive properties. Investigations were conducted on its X-ray spectrum by external excitation, the crystal structures of the element and of its compounds, and the optical spectral lines. Also several chemical compounds were prepared in pure form and studied thermodynamically and otherwise, confirming the general analogy with rhenium.

In 1952 it was reported by Paul W. Merrill that spectra of stars of the S type show strong technetium lines. The astrophysical reason for this remarkable fact is not known.

**BIBLIOGRAPHY.**—C. Perrier and E. Segrè, "Some Chemical Properties of Element 43," *J. Chem. Phys.*, vol. 5 (1937); G. Friedlander and J. W. Kennedy, *Nuclear and Radiochemistry*, 2nd ed. (1964); E. Anders, "Technitium and Astatine Chemistry," *Am. Rev. Nucl. Sci.*, vol. 9 (1959) (Eo. S.)

**TECHNICAL EDUCATION** is concerned with teaching applied sciences, special training in applied science, technical procedures, and skills required for the practice of trades or professions, especially those involving the use of machinery or scientific equipment. Technical education emphasizes the understanding and practical application of basic principles of mathematics and science rather than the attainment of proficiency in manual skills. It has as objectives the preparation of graduates for occupations between the skilled crafts and the engineering or scientific occupations. Technical schools or institutes usually offer instruction to students beyond school age, although many variations exist. In most countries the basis, at least, of technical training is offered at the secondary level, often in special schools, as the technical secondary schools of Great Britain, and some countries include technical education in the elementary curriculum. At the other end of the scale, it is usually considered to be below the professional level, but there is no clear dividing line. The picture is further complicated by the fact that many institutions that are designated colleges offer work below the college level, and some that are designated technical institutes or polytechnics offer advanced scientific and professional work, as, for example, the Massachusetts Institute of Technology.

For this article, the following definition has been used: Technical education is that education offered in post-high school curricula that generally are one to three years in length, are terminal in nature and not designed to lead to a baccalaureate degree, and are offered in a wide variety of institutions, such as technical institutes, junior colleges, night schools, extension divisions of colleges and universities, and proprietary schools. Variations from this are indicated.

Under this definition technical education may be distinguished from vocational education, which places major emphasis upon imparting manual skills to an individual to prepare him for a single occupation or trade. Vocational education is generally offered in vocational, or trade, schools or comprehensive high schools. Technical education may also be distinguished from professional education, which places major emphasis upon the theories, understanding, and principles of a wide body of subject matter designed to equip the graduate to practise in such fields as medicine, law, and engineering. Professional education necessitates the completion of at least four years of college and generally requires a significant amount of graduate work beyond the baccalaureate degree. (For programs at the secondary level, see VOCATIONAL EDUCATION. For technical education at the college level, see HIGHER EDUCATION; ENGINEERING EDUCATION.)

Graduates of technical curricula may be roughly classified as follows: (1) engineering and science aides, such as draftsmen, designers, laboratory technicians; (2) technical supervisors, such as foremen, chief inspectors, production supervisors; (3) technical specialists, such as time study men, methods analysts, quality control men; (4) technical salesmen.

A narrower definition of technical education normally implies those curricula that are engineering related, but the term is also sometimes more broadly and loosely used to embrace nonengineering related curricula from one to three years in length in agriculture, applied and graphic arts, business, education, and health services.

## UNITED STATES

The need for technical education evolved as a result of the Industrial Revolution, and, beginning early in the 19th century, a movement for the education of the workingman took place in both England and the United States. A number of mechanics institutes were founded, whose purpose it was to impart technical information and skills to farmers and mechanics. Some of the early mechanics' institutes that sprang up in the larger industrial centres were The General Society of Mechanics and Tradesmen founded in New York in 1820; the Maryland Institute in Baltimore, 1825; Franklin Institute in Philadelphia, 1824; and Ohio Mechanics Institute in Cincinnati, 1828. Most of these institutions flourished briefly and then closed. Ohio Mechanics Institute (now called Ohio College of Applied Science) is the only survivor still in existence that has a continuous history of offering training for technical occupations.

A significant early impetus given to technical education in the United States was the passage of the Morrill Act in 1862, which granted large blocks of land to the several states for the support of public colleges of agriculture and mechanic arts. With this assistance many of the states established land-grant colleges, and most of these institutions in the early years offered much education that was technical in content and level (see LAND-GRANT COLLEGES AND UNIVERSITIES).

Numerous private institutions founded in the years preceding and following the Civil War functioned largely as technical institutes but have since become more conventional four-year engineering and science schools. These include Pratt Institute, founded in 1887; the Rochester Institute of Technology, which traces its history back through the merger in 1891 of the Rochester Athenaeum, 1829, and Mechanics Institute, 1885; the Polytechnic Institute of Brooklyn, founded 1854; Cooper Union, 1859; Drexel Institute, 1891; and Carnegie Institute of Technology, 1900.

## STATUS OF TECHNICAL EDUCATION

The identification of "technical education" as having a level and content of its own was initially stimulated by a report, "A Study of Technical Institutes," published by the Society for the Promotion of Engineering Education (SPEE) in 1931. Although the report dealt with the technical institute as a type of educational institution, it also identified this level of education as "occupying an area between the skilled crafts and the highly scientific occupations."

The years since this report have witnessed a more rapid growth of technical education than the previous century. This has been due in part to: (1) The 1931 SPEE study of technical institutes; (2) The rapid development of scientific and engineering industries which have created a need for trained technicians; (3) The tremendous need of the armed forces for technicians; (4) The accreditation of technical-terminal curricula by the Engineers Council for Professional Development; (5) The growing body of literature devoted to this type of education; (6) The granting of the associate's degree for technical-terminal programs, giving status to this level and type of education; (7) The report of the National Survey of Technical Institute Education (published in 1959) conducted for the American Society of Engineering Education under a grant from the Carnegie Corporation.

Surveys of U.S. technical education reveal that the engineering-related curricula enrolling the largest numbers of students were electrical technology, mechanical technology, and architectural and civil technology. The largest enrollments in nonengineering curricula were business, health services, and education. In these surveys slightly more than three-fifths of the students were enrolled on a full-time basis, and more than three-fifths were in publicly controlled institutions. (L. F. Sh.)

## UNITED KINGDOM

**England and Wales.**—Technical education in the modern sense did not develop in England on any substantial scale until the last decade of the 19th century. The mechanics' institutes founded in great numbers from 1823 to about 1860, were intended to instruct workingmen "in the scientific principles of arts and

manufactures," but for the most part they quickly became diverted to social and literary rather than industrial education. The Great Exhibition at the Crystal Palace in 1851, which confirmed fears that Great Britain's industrial primacy was being threatened, led the government to establish a science and art department, but the grants that it distributed did little beyond developing an arid examination system.

The 1867 international exhibition at Paris shook British complacency. It led to the founding, in 1880, of the City and Guilds of London Institute to promote the teaching of applied science. In 1883 the institute opened the Finsbury Technical College for the training of artisans and in 1884 the Central Training College at South Kensington to train technical teachers and the higher ranks of industry. Meanwhile, quite independently, Quintin Hogg opened in 1882 the Polytechnic in Regent Street, London.

The Technical Instruction Act, 1889, empowered the newly created county councils and the county borough councils to give limited aid to technical education out of public funds. In 1891 the Local Taxation (Customs and Excise) Act unexpectedly made further large sums of money (popularly called "whiskey money") available for this purpose. Consequently, the decade 1889-99 saw great activity in the provision of buildings for the teaching of applied science and technology. In addition to public effort, funds provided by the City of London Parochial Charities Act, 1883, aided the building in London of more polytechnics.

In 1899 the Board of Education Act created a single national department charged with the supervision of public education throughout England and Wales. The Education Act, 1902, similarly made the county and county borough councils general purpose education authorities, responsible for supplying or aiding the supply of secondary and technical as well as elementary education. The preoccupation of the board of education and the local education authorities with the development of the newly established secondary system considerably slowed down provision for technical education for more than ten years. Nevertheless, about 1905 trade schools for boys and girls leaving elementary schools began to be established in London, Middlesex, and elsewhere; and in 1913 these schools were made eligible for grant as "junior technical schools."

The first decades of the 20th century were marked by development of technical education by local education authorities, but also by continuing prejudice against it on the part of the public at large, who supposed that it qualified students only for menial work. As a result, the secondary technical schools, though vigorously championed by certain enthusiasts, appeared unlikely ever to match the grammar schools in numbers or reputation. But World Wars I and II, and the demand in each for skilled personnel, brought a gradual recognition that technical education was vital to an industrial society. Technical studies began to be taken up in secondary schools of all types; and the growing preoccupation of the universities with them added to their prestige. By the 1960s a distinct pattern of strictly technical institutions could be seen. There were about 300 local technical colleges (besides 7,600 local evening institutes), and about 160 area and 25 regional colleges offering increasingly advanced work. The Council for National Academic Awards, formed in 1964 and empowered to grant its own degrees, promised increasing status for technical studies at the higher levels. Outside the state system there was a flourishing body of private correspondence colleges offering a wide variety of technical courses.

**Scotland.**—Modern technical education in Scotland began with the founding by George Birkbeck in 1800 of a class for instructing Glasgow operatives in "mechanical and chemical philosophy." In 1823 this class broke away from the Andersonian Institute, to which it was attached, to form the first mechanics' institution. Two years previously there was opened in Edinburgh the School of Arts, claimed to be the first institution in Great Britain founded expressly to give scientific instruction to workingmen.

Until 1897 the English science and art department covered Scotland as well, and consequently statutory development of technical education was broadly parallel with that in England, except that under the Educational Endowments (Scotland) Act, 1882, money

was provided for establishing and maintaining technical schools. The Andersonian Institute and the Glasgow Mechanics' Institution were merged in what became the Royal Technical College, Glasgow, and the School of Arts in the Heriot-Watt College. The former, since 1956 called the Royal College of Science and Technology, Glasgow, in 1964 was chartered as the University of Strathclyde.

Codes of regulations in 1899 and 1901 organized elementary technical instruction in "continuation classes." To encourage advanced work the 1901 code provided that outstandingly good and well-equipped technical colleges could be exempted from its regulations and grant aided on special terms. The Education (Scotland) Act, 1908, recognized 11 of these "central institutions," as they became known.

In the 1960s technical education was being provided in 16 central institutions, including agricultural and veterinary colleges, and in over 1,100 "continuation class centres."

**Northern Ireland.**—Before 1922 education throughout Ireland was regulated from England. In the 19th century, despite the nonindustrial character of the country, technical education developed remarkably. It received an added stimulus in 1899 when a Department of Agriculture and Technical Instruction was created. In 1922, 39 technical schools managed by local authorities were handed over to the Northern Ireland government. They included the Belfast College of Technology, one of the largest and best in the British Isles.

The Education (Northern Ireland) Act, 1923, further stimulated technical education by abolishing the restriction on expenditure to a 2d. rate and merging it in the general expenditure of the local authorities. Junior technical and commercial schools expanded, especially in the provision of day classes.

The Belfast College of Technology prepares students for degrees in engineering and related subjects offered by the Queen's University. Among its students are also trades scholars, who are apprentices granted scholarships by the Ministry of Education for extended courses. Each of the counties is well equipped with technical schools, County Down, for instance, having 8, with 25 subsidiary centres.

## REPUBLIC OF IRELAND

The Department of Education set up in 1924 took over the functions of the Technical Instruction Branch of the Department of Agriculture and Technical Instruction established by the Agricultural Technical Instruction (Ireland) Act, 1899. Following the report of the Commission on Technical Education, issued in 1927, which noted especially the lack of technical instruction in rural areas, a system of rural continuation schools was developed, offering full- and part-time classes to meet the needs of their localities. Technical colleges and schools maintained by local authorities were established in all cities and large towns.

## BRITISH COMMONWEALTH

**Australia.**—With increasing industrialization, much attention was paid to technical education, especially after 1940. In all states there are technical secondary schools or courses, and part-time training schemes, from three to five years in duration, for apprentices.

The University of Queensland runs correspondence courses in technical education up to degree standard. Altogether, by the 1960s, Australia had more than 200 technical schools and colleges.

**New Zealand.**—At the secondary level there are technical high schools in the large towns; in the smaller ones consolidated schools offer technical courses. There is a Technical Correspondence School in Wellington.

(See also **NEW ZEALAND: Administration and Social Conditions: Education.**)

**Canada.**—In both English and French educational systems there are technical high schools and trade schools at the secondary level. Post-secondary technical institutes numbered more than 30 in the 1960s and had an enrollment of 12,000 students. The Nova Scotia Technical College and the agricultural, pharmacy, and veterinary colleges in Ontario are of university status, as is Mac-

donald College, the agricultural faculty of McGill University, Montreal, Que.

The western universities and New Brunswick have schools of engineering and agriculture. Newfoundland has a technical college at St. John's for the fishing industry. (See also CANADA: *Administration and Social Conditions: Education.*)

**India.**—In many elementary and some secondary schools instruction in handicrafts was made compulsory during the 1950s. Further technical education was provided in universities and technical institutions at four levels: vocational training; diploma courses; first degree courses; postgraduate courses.

The responsibility for education was assumed by the states, but the central government, through the All-India Council for Technical Education, coordinated and improved facilities. It maintained the Delhi Polytechnic and established the Institute of Technology at Kharagpur in West Bengal (1951) and those at Bombay (1958), Madras (1959), and Kanpur (1960). The number of institutions awarding various grades of diploma in engineering and technology had risen by the 1960s to more than 350.

**Pakistan.**—At the time of partition in 1947 Pakistan had three engineering colleges and some industrial institutes. The Council of Technical Education prepared a national development plan. In 1951 the first of six technical secondary schools was opened at Karachi and the establishment of the Karachi Polytechnic (assisted by the Ford Foundation) begun. Engineering colleges were established in the Punjab and the North-West Frontier Province in the 1950s. A polytechnic institute was founded at Dacca, East Pakistan, in 1955, and another at Chittagong in 1962. In 1961, schools of engineering and technology were founded in East Pakistan and West Pakistan. The Swedish Pakistani Institute of Technology, Karachi, was established in 1958. Some Pakistanis were training abroad under the United Nations Program of Technical Assistance and the Technical Co-operation Scheme of the Colombo Plan. By 1964 East and West Pakistan each had a directorate of technical education, and polytechnic evening classes had been begun for practising craftsmen, who were also to be assisted by mobile workshops. The polytechnics also were training technical teachers, and training colleges for polytechnic and engineering college teachers were being set up in both East and West Pakistan.

**Other Commonwealth Countries.**—After World War II much effort was made, by governments, UNESCO, and other agencies, to overcome the difficulties for technical education in developing countries resulting from insufficiency of general primary and secondary skills among pupils and lack of buildings, equipment, and staff. In the 1960s training for African technicians was being provided in the United Kingdom under the Special Commonwealth Assistance Plan for Africa (SCAPA). Great Britain also provided specialist advisers and teachers by means of the Commonwealth Educational Co-operation Scheme; and under the Overseas Service Aid Scheme trained technical staffs could be retained by governments until enough local staff had been trained. By the 1960s more than 5,000 technicians were training in the United Kingdom under the Colombo Plan for Co-operative Economic Development in South and South-East Asia.

**African Countries.**—By the 1960s Ghana had a technical university (the Kwame Nkrumah University of Science and Technology, founded 1961) and 9 technical institutes. Nigeria had more than 20 trade training institutes, as well as technical colleges in Lagos and Ibadan. Scientific and technical studies figured large in the programs of the universities of Ahmadu Bello (1962), Ibadan (1962), Ife (1961), Lagos (1962), and Nigeria (1960). Sierra Leone had 2 technical institutes, at Freetown and Kenema. Uganda had one technical college and numerous centres for rural trades and homecraft. Kenya had a polytechnical college and a technical institute in Nairobi. Malawi had a college of commerce.

## CONTINENTAL EUROPE

Technical education is highly organized throughout the continent of Europe. France, West Germany, Italy, and the U.S.S.R. may be taken as examples.

**France.**—Technical education was brought under state control

in 1892 and codified by the *Loi Astier* of 1919. Provisions were made for three main levels: apprenticeship, intermediate, and higher. The first and second were usually entered from the elementary school; the third was open only to students possessing the baccalauréat awarded at the end of a secondary course.

In the 1960s pupils 13–18 years of age could obtain three-year courses in *collèges d'enseignement technique*; and five-year courses in *lycées techniques* or in the technical departments of other secondary schools. A sizable minority of the *collèges* and *lycées* was private. Higher technical instruction is given at national schools, such as the École Polytechnique, the École Centrale des Arts et Manufactures, whose aim is to produce future industrial leaders, and the Écoles Nationales d'Agriculture at Grignon, Montpellier, and Rennes. There are similar national schools for horticulture, veterinary science, aviation, and mining.

**German Federal Republic.**—During the 19th and early 20th centuries Germany built up a comprehensive national system of vocational training for workers of all grades. The Hitler regime perverted this, and the collapse of Germany in 1945 temporarily laid it in ruins. It was later built up again on similar lines, at varying rates in the different *Länder*.

In the 1960s apprentices and other young people were receiving theoretical technical training in the *Berufsschulen*. These were post-elementary vocational schools giving obligatory courses lasting three years or until the end of apprenticeship, when an examination was taken. Next came the *Berufsfachschulen*, which offered full-time diploma courses lasting from one to several years, mostly to girls leaving elementary school, with particular stress upon domestic subjects, office routine, training in fine handicrafts, and artistic training. The *Fachschulen* provided higher technical education for those with practical experience, the course varying in length from six months only to eight six-month periods. The universities had technical faculties, and several of the technical colleges had university status.

**Italy.**—During the 1960s the number of technical training institutions in Italy greatly increased. Pupils being transferred from elementary to secondary school at 11 years of age could choose a program with a technical-scientific bias; and for pupils more than 14 years old there were industrial schools, vocational training institutes with special schools attached, and technical institutes. There were about 1,500 vocational and technical industries. Students holding vocational and technical diplomas could enter the universities, where students of science and engineering were beginning to outnumber others, a trend encouraged by the government. The government-maintained polytechnics of Milan and Turin had university status.

**U.S.S.R.**—The first technical institutes in Russia were founded in the 18th century. A system of lower and secondary technical schools was created by Alexander II (reigned 1855–81), in three grades: crafts and industry schools for workmen; lower technical schools for foremen; and middle technical schools for assistant engineers.

**Soviet Period.**—With much increased industrialization the need for technicians was acutely felt. The Soviet government created in 1920 a State Committee of Vocational Education, which built up a network of technical schools. In 1929 these were transferred to the State Council for Economy and subsequently to commissariats of industry and transport. The government established secondary *technicums* side by side with factory schools for the training of skilled workmen. With the establishment of the Federal Ministry of Higher Education, all technical institutes throughout the U.S.S.R. were classified to teach: (1) technology; (2) light industry; (3) construction and architecture; (4) mining and metallurgy; (5) transport; (6) agriculture and forestry.

By mid-20th century, technical education was being given, without charge, to young people 14–17 years old in 1- to 3-year courses in urban and rural vocational training schools; to workers following 6-month vocational courses in their factories; and to more advanced and older students in a network of secondary special and higher educational establishments throughout the U.S.S.R., and through evening or correspondence courses. A majority of students received state allowances, the best receiving larger stipends.

Vocational training pupils (who in the 1960s numbered more than 1,500,000) were given uniforms, and hostel accommodation with board, and were paid for factory work done as part of their training. They were guaranteed posts in their speciality on qualifying. Students at secondary technical schools (both men and women) were enrolled between 14 and 30 years of age and had to have a minimum of 8 years' schooling, their technical course being in this case of from 3 to 4 years. For students with a secondary school background the course is from 1½ to 3 years. There is no age limit for the evening and correspondence courses. Higher technical students take 5- to 6-year courses in polytechnical and other special establishments; at the engineering faculties of certain universities; and at colleges connected with industrial enterprises. Workers qualifying through evening or correspondence courses receive extra paid leave of absence for periods from 20 days to 5 months to enable them to prepare for examinations or present their diploma theses. (See also UNION OF SOVIET SOCIALIST REPUBLICS: *Administration and Social Conditions: Education.*)

#### MIDDLE EAST AND NON-COMMONWEALTH AFRICA

Much of the technical training in the Middle Eastern countries has been provided by oil companies and other commercial interests. Nevertheless, government systems were developing in the 1960s. Syria had more than 40 technical schools, and its University of Damascus included faculties of engineering and agriculture. Lebanon's trade schools included one in hotelkeeping. Tunisia had 66 technical schools. The United Arab Republic opened an Institute of Technology at Helwan in 1963 and trained semiskilled workers at about 50 vocational training centres. Vocational studies were prominent in the schools of Iraq and Israel. The Israel Institute of Technology in Haifa had a staff of more than 600. In Saudi Arabia the Higher Institute of Technology at Riyadh, founded in 1962 through the UN Special Fund, was training 1,000 engineering students, some of them as teachers; an Arabic technical terminology also was being composed there. Turkey had trade schools, technical schools, and evening classes. In Istanbul there was a technical university. The Middle East Technical University, at Ankara, was founded in 1956. (See also TURKEY: *Administration and Social Conditions: Education.*)

Among the more important African institutions may be mentioned the faculty of science and technology at the University of Madagascar at Tananarive (founded in 1961); the Centre d'Apprentissage and Lycée Technique at Dakar in the Republic of Senegal; the École Industrielle at Mogadishu in the Somali Republic; the Collège Technique and Lycée Technique d'État at Brazzaville, Congo (Republic); the Lovanium University's faculties of engineering and agriculture and the telecommunications school (founded in 1962), both at Léopoldville, Democratic Republic of the Congo.

In the Republic of South Africa the Department of Education, Arts and Science was responsible by the 1960s for technical colleges, technical and commercial high schools, and vocational schools for whites, in the principal cities; and a technical college for Indians at Durban. Technical studies could be pursued by whites at the universities; Indian students could take commercial subjects at the university college founded for them at Durban in 1960. The Department of Bantu Education assisted the development of the Bantu homelands by offering two-year courses at more than 50 vocational training schools for Bantu. Further schools were founded in 1961 in the Transkei, Ciskei, Northern Transvaal, and Zululand. The total of trainees was more than 2,000.

(H. C. D.; L. R. Bu.; X.)

#### CHINA AND JAPAN

Technical education in Communist China has received the highest priority because it is considered essential to the goal of economic development through industrialization. Its characteristics include strict planning by the state, in accordance with the needs of economic development, and phenomenal expansion in the number of schools and proliferation of fields of specialization.

Many different types of technical schools have been established on the secondary level for increasing numbers of students in the

15-18 age group. On the mass level, thousands of so-called Red and Expert colleges and spare-time schools in rural areas were opened to serve the dual purpose of eradicating illiteracy and providing fundamental technical training in industrial and agricultural undertakings. Thus, technical education in China covers a wide range, from the training of technologists in such fields as electronics to the dissemination of information concerning the simplest labour-saving techniques.

Ideological considerations and shortage of teaching staff and facilities have compelled the Communist state to adopt the principle of "combining education with productive labour," by which students on higher and secondary levels are required to receive their practical training in industrial plants where they engage in productive labour, while industrial workers are given formal technical education in schools. The scene in technical education is one of total mobilization of trained personnel and existing facilities.

Technical education in Japan differs significantly from that of China, due principally to the advanced level of Japanese education as a whole, its high level of industrial development, and its free access to Western technical knowledge. These factors have been responsible for the exceptional rate of economic growth in postwar Japan and are reflected in the character of its technical education.

Based on an industrial system that already compares favourably with advanced Western countries, Japan's technical education aims at the application of modern science and technology to all aspects of economic life; the educational program carried on by the Future Farmers of Japan is an example of this effort in the field of agriculture. Another major objective is the introduction of more and newer technical subjects into elementary and secondary schools. Curriculum revisions along this line were completed for elementary schools and for lower secondary schools in the early 1960s, thus covering the entire period of compulsory education. Technological education also is provided both on the upper secondary school level and the junior college level as a part of the endeavour to extend the benefits of technical education, through their students, to all aspects of Japanese life.

**TECHNICAL SCHOOL** (GREAT BRITAIN): see **SECONDARY EDUCATION**; **EDUCATION**, **HISTORY OF**.

**TECHNOLOGY, HISTORY OF.** The history of technology is the story of man's long and painful efforts to control his material environment for his own benefit. Man has been able to do this, as no other creature has, by two means: first, the use of tools; and second, the application of reason to the properties of matter and energy. For many thousands of years, however, his progress in technology was made by trial and error, i.e., by empirical advance, which nonetheless made possible impressive achievements. It was only toward the end of the 18th century that technology began to become applied science, with results in the 19th and 20th centuries that have had enormous influence.

There has always been a close interaction between the form of man's society and the technology which it produces. The political, social, economic, and even religious organization of a culture influences the kind of problems and goals that are set before the engineer and the importance and magnitude of the undertakings with which he is concerned. The technology of a culture is also strongly influenced by the geography of the area in which it arises and by the materials available for engineering work.

By the study, in these broad terms, of the technology of earlier times, often quite different from our own in geography and physiography and in political, social, and economic organization, we can better understand the interaction of modern man's efforts to control both his material and his human environment in order to give himself the kind of life that he believes to be worth having. (See **CIVILIZATION AND CULTURE**.)

Up to the 18th century the technology of all cultures had been based upon craft skills, patience, much labour, and remarkable ingenuity. These societies may be termed the "Craft" Societies. Since the 18th century our technology has developed the use of machines, power, precision, iron, and applied science into an entirely new place in a society which has also changed in very important and fundamental ways. This new way of life may be designated the "Industrial" Society.

What we are concerned with, then, is the story of man's rise as a tool-using and reasoning animal, from the first true man with a stick or stone in his hand up to a modern man controlling the means of man's production and man's destruction.

This article is organized as follows:

#### I. Prehistoric Technology

1. Paleolithic
2. Neolithic
3. The Bronze Age

#### II. The Urban Revolution in the Tigris-Euphrates and the Nile Valleys

##### A. The Tigris-Euphrates Valley

1. The Social Evolution
2. Ziggurats

## I. PREHISTORIC TECHNOLOGY

**1. Paleolithic.**—The material wants of prehistoric man were clearly less complex than those of civilized man. He therefore needed much simpler technical equipment to control his material environment to his own benefit. He used wood, stone, bone, leather, reeds, vines, clay; and, much later on, metals. All these materials required the use of tools, except for reeds, vines, and clay, which could be worked by hand. Significantly, these same materials remained the basic materials of technology until the last few centuries. During this prehistoric period technical progress was very slow, yet some very important discoveries and inventions were made.

The earliest evidence of man's use of tools comes from the remains of stone tools, from which this age takes its name—Paleolithic (*q.v.*), or Old Stone Age (see also *ARCHAEOLOGY: Prehistory*). But he also used tools of wood, bone, and other materials, most of which have perished.

Paleolithic man had certain other important technological innovations. Evidence of the use of fire has been found in the oldest known remains of man. Later he built fireplaces, some of which were designed to provide good draft. He had considerable knowledge of foods—he knew which were edible and which poisonous. He lived in caves for some time and then devised crude shelters, in some areas made of skins. Remains of stone scraping tools and excellent bone needles show that he made clothing out of animal skins.

Paleolithic man caught fish with spears and with hook and line. He caught animals with ingenious traps and used the spear-thrower and the bow and arrow to extend the range of his hand and arm.

In addition to his technological achievements, early man made social and cultural advances. Family, clan, and tribal organizations existed, and there was division of labour, at least among the sexes. Clay figurines have been found which show an interaction of art and magic. The existence of burial rites and other ceremonies indicate religious development and probably a priesthood—the first group to be freed, at least partially, from the responsibility for its own protection and food supply.

The most important technical contribution of the Paleolithic is the development of tools. The use of stone tools probably began with the recognition that stones cracked and split by nature could serve useful purposes better than wood and bone tools. By about 100,000 years ago man was clearly making stone tools for his own use (see further *FLINT AND OTHER STONE TOOLS*). This was a most important transition, for while a few other animals use tools, only man makes them for his own use. Flint tools predominated because this material could be worked by hammering with stone, wood, or bone to strike off coarse chips of flint or to force off smaller chips by pressure. Skills gradually developed until by the end of the Paleolithic the tools show delicacy of workmanship, sometimes are even decorated, and many have handles worked on them. By this time man was also drilling bone, shell, and even stone. He then had a fairly complete set of carpenter's tools—axes, adzes, gouges, and drills. Modern tests using actual Paleolithic tools have shown them to be quite efficient.

**2. Neolithic.**—About 10,000 B.C. a series of technological and social changes, which we call the Neolithic (*q.v.*), or New Stone Age, began in various parts of the world. Cultures technologically Neolithic were to arise later in many other parts of the world, e.g., those of the North American Indians when they were first discovered. These cultures were enormously richer than those of the Paleolithic.

The basic distinction between the Neolithic and the Paleolithic was the development of animal husbandry and agriculture. Man learned to domesticate sheep, goats, cattle, and pigs for food. Farming appeared, as well as fishing, hunting, and collecting wild seeds and berries for food. Neolithic man discovered that wild seeds could be planted and then cultivated, thereby providing greater convenience and a much greater yield, with much less labour. He found also that irrigation was beneficial and that certain plants such as wheat, rice, millet, corn, yams, and squash were most satisfactory for agriculture. He even discovered the merits of crop rotation and fertilization.

The results of this agricultural revolution were far-reaching. The food surplus thus produced called for special buildings for storage. Changes took place in the way in which man prepared his food: the saddle quern appeared for grinding grain, and bread-making involved the use of yeast and a primitive oven. Fermented liquors were produced and beer was definitely known by 3000 B.C.

HIRMER FOTOARCHIV, MÜNCHEN

EGYPTIAN LIMESTONE STATUETTE. FROM ABOUT 2500 B.C., IN THE CAIRO MUSEUM. SHOWS A SERVANT GIRL OF ESTATE OWNER UR-IR-EN USING A SADDLE QUERN FOR GRINDING GRAIN

This greater food supply led to an overall increase in population and in the size of the social unit. The helter-skelter arrangement of the Paleolithic village was replaced by houses arranged in patterns along definite streets, with buildings constructed of mud, reeds, logs, stone, or clay. Protection was improved by stockades and ditches. Spinning thread and weaving cloth also began in Neolithic times, and clay was formed into vessels and then heated to make a firm, hard pottery.

**3. The Bronze Age.**—The Bronze Age (*q.v.*), which began about 4000 B.C. in the Near East, was remarkably fertile in fruitful inventions and discoveries, for its achievements made possible a basic economic and social reorganization of society which can be styled the Urban Revolution. Among its technical contributions were at least six of great importance: (1) the copper and bronze from which the Age takes its name and which involved the whole art of casting and metallurgy; (2) harnessing of animal power (the ox, the ass, and the horse); (3) wheeled vehicles, with their greater efficiency in moving heavy loads; (4) the sailboat, which provided better water transportation and was the first use of wind power on a large scale; (5) the potter's wheel, with its greater possibilities for pottery; and (6) bricks, which came into use for building as early as 4500 B.C. (See also *ARCHAEOLOGY: Neolithic and Bronze Ages in Europe*.)

Copper and then bronze were found to be malleable, i.e., they could be hammered into shape, beaten into sheets, and cut into pieces. Man next made one of the most important discoveries: these metals could be formed into sharpened tools. Unlike his other materials, copper and bronze could be melted and cast to form almost any desired shape and size. They were also more durable than wood or stone, especially for tools, which could be easily resharpened by rehammering or grinding.

But to utilize the advantages inherent in copper and bronze required a complex of ingenious inventions. A furnace capable of high temperatures from an air blast was needed for melting the metals for casting and for reducing them from their ores, and crucibles and molds had to be designed. The practical metallurgy of separating the metal from its ores was also developed.

Once these techniques had been worked out for copper and bronze, it was not too difficult to use silver, lead, and tin in a similar way. Iron was a more difficult problem, because much higher temperatures were required. But it was soon possible to produce nonferrous alloys of importance, though brass did not appear until much later.

This metallurgical activity—casting, reduction, and alloying—involved a technology far more abstruse and demanding than that of the potter, weaver, or boat builder, to say nothing of the farmer or herdsman. Metallurgical processes also seemed mysterious and magical, even to the metallurgists. It is not surprising that in these early societies, as among many contemporary primitive people, metallurgists and miners were more than craftsmen, more than specialists, and somewhat set apart. Very early, therefore, they had a special status and were the first class after the priest-magicians to be withdrawn from direct food production to engage in a full-time occupation considered to be socially worthwhile. They were, in fact, the first engineers, and their skills were of great importance to Bronze Age culture.

By 3000 B.C. the wooden plow was being pulled by oxen. The ox was used for this purpose before the horse because his broad shoulders permitted an easy attachment to a simple harness. The ox-drawn plow was of great importance, for plot cultivation was replaced by field cultivation. Agriculture was then wedded to stock

A 12TH-CENTURY DRAWING OF A HEAVY-WHEELED PLOW WITH A TEAM OF OXEN HARNESSSED BY A YOKE ENTIRELY UNSUITED FOR HORSES. FROM HERRAD VON LANDSPERG, "HORTUS DELICARIUM"

raising, and it became necessary to raise food for these animals as well as for humans. The animals also provided fertilizer for the fields. Handling the ox and the heavy plow required a man's strength, so that agriculture came to be principally men's work rather than women's.

In using draft animals a basic discovery had been made—that man could control and use to his own advantage a motive power other than his own muscles. Oxen could also be used to pull a sledge, and horses and asses could carry loads. Along with this use of animal power went one of the most critical inventions of all time. How, when, and where they first appeared is not known, but two- and four-wheeled vehicles were in use in the Tigris-Euphrates culture prior to 3000 B.C. (see further WHEEL). By that time oxen, horses, and asses were used in combination with either the sledge, the wagon, or the chariot to provide motive power for land transportation in a form not to be superseded in its basic features until the Middle Ages in Europe.

Boats driven by sails appeared in Egypt prior to 3000 B.C. Sailed, rowed, paddled, or hauled boats became available to transport heavy and bulk loads economically by water. This revolution in transportation led to a great expansion of trade, especially in the import of raw materials and the export of craft goods, which in turn spurred the growth of the new classes of traders and artisan-craftsmen.

One craft influenced by the demand for export goods was that of the potter. Hand-formed pottery had been made for a long time, principally by women, but with the invention of the potter's wheel this work was taken over by the men, who served a long apprenticeship to develop the necessary skill. Thus a new full-time craft was born.

The potter's craft is another example of the trend toward increased specialization, changes in the economic relations of the sexes, and profound changes in the organization of society from one based on agriculture to one based on trade and craft manufacture. The power of the king, the war chief, and the priest was threatened

and gradually replaced by the power of capital, that is, the power of wealth not founded upon land. It was this profound change in technological, social, economic, and political life that constituted the Urban Revolution. It was this accumulation of wealth, improvement of technical knowledge, increasing specialization of craft skill, and expanding trade that made civilization possible and so provided a basis for large-scale engineering projects in the great river cultures of the Tigris-Euphrates and the Nile.

## II. THE URBAN REVOLUTION IN THE TIGRIS-EUPHRATES AND THE NILE VALLEYS

The first appearance of large units of organized society in the Old World occurred in the valleys of the Tigris-Euphrates and the Nile. Although the actual areas and populations concerned were not great, these social units were most important because they produced a buildup of technical potential and its synthesis in the Urban Revolution, an entirely new form of society which we call civilization.

Civilization first appeared at these particular places at this time because of a number of elements, the most important being the presence of a river that could be used for transportation and irrigation. There was also a valley of alluvial soil in which agriculture was relatively easy and very productive. Moreover, the important advances of the Bronze Age formed some of the technical foundations of these civilizations.

The Urban Revolution led to the appearance of cities based on specialization, a craft economy, trade, and the new economic and social organizations to which these factors gave rise. Without the Urban Revolution the new technical devices would have been just conveniences, the new materials only luxuries, and the new crafts could not have flourished.

### A. THE TIGRIS-EUPHRATES VALLEY

In the Tigris-Euphrates Valley the river flows down to the Persian Gulf, bringing with it rich soil that forms extensive alluvial deposits. The area flooded periodically, but with proper flood control, drainage, and irrigation, a substantial surplus of food was produced. These river-control measures marked the beginning of civil engineering.

Although the valley lacked stone or flint for tools and stone or wood suitable for building, there was an ample supply of clay for bricks and a good supply of copper. The people built wheeled vehicles for land transportation and small boats for navigating their difficult river, marking the beginnings of naval architecture

THE REGIONS OF THE TIGRIS-EUPHRATES AND NILE VALLEYS

and mechanical engineering. Architectural engineering originated in their need for construction of large buildings, granaries, workshops, and temples, and for building their great city walls for defense.

**1. The Social Evolution.**—In exploiting the resources of their valley, these people evolved a society in which the temple priests played a most important part in both their economy and their technology. The agricultural organization, together with its flood control and irrigation systems, was managed largely by engineer-priests who also supervised the construction of the great temples and ziggurats (see below). Other technical priests supervised the specialized craft shops of bakers, brewers, smiths, wool washers, carders, spinners, weavers, and so on. Tools, wagons, boats, plows, plow animals, and stud bulls were owned by the temple. This collectivistic organization ensured a rational exploitation of the land, systematic maintenance of canals and irrigation systems, and the production of an agricultural surplus for trade.

The traders and merchants were independent of the temple priests because by 3000 B.C. certain imports such as copper, bronze, timber, and stones had become necessities, and the extent and volume of trade in those commodities were considerable.

Although the Tigris-Euphrates Valley forms a natural geographic and economic unit, it was seldom politically so united. Throughout most of its history a number of its powerful cities were engaged in constant warfare. The wars produced a labour force of slaves, a demand for metal weapons, and a need for elaborate city walls for defense.

This complex society had to invent writing to maintain records of taxes, shares due and paid in, and so on. It also required a standard system of weights and measures and a balance for weighing. While farmers needed a calendar and a system of time reckoning, engineers needed surveying tools and methods for laying out canals, irrigation systems, temples, and defensive walls. The engineer also had to have a mathematics capable of calculating volumes, areas, and angles. This led to the beginnings of pure science.

There was also a high level of craftsmanship. Goldsmiths could solder, and they worked in gold ribbon or wire, producing fragile chains and delicate filagree work. The coppersmiths could hammer, cast, and make specialized tools such as axes, adzes, chisels, gouges, drills, knives, saws, nails, clamps, and needles. Their jewelers could drill the hardest stones and engrave them for seals, and sculptors worked in as difficult a stone as basalt. The carpenters constructed boats, chariots, wagons, and even harps and lyres of the highest quality, and potters produced coloured glazes, some of which were exported.

In the Tigris-Euphrates culture, three things were of special technological interest: the ziggurats, large pyramidlike structures dominating the cities; the enormous defense walls, which reflected the political instability of the valley; and the extensive systems of irrigation and flood control, which formed the basis of an agricultural economy.

**2. Ziggurats.**—The ziggurat was a religious structure, always associated with a temple. Although other peoples built similar structures in other parts of the world, there were important differences among them. The Egyptian pyramid was made of stone, with inside chambers, and its purpose was to preserve an embalmed body; it was a tomb, nothing more. The Maya-Aztec culture in Central America also constructed large brick or stone pyramids that sometimes had chambers, but they were intended to serve as religious altars. The ziggurat was always made of brick and had

no internal chambers. It too served as a kind of altar, but its primary purpose was to provide a suitable home for a god whose original home had been on a mountain. The ziggurat was, then, a kind of artificial holy hill, and each city of this culture had its own. Its sloping sides and terraces were landscaped with trees and shrubs (hence the Hanging Gardens of Babylon).

The ziggurats and temples were constructed with a core of sun-dried brick set in mud. The outer faces were consolidated by hammering into the wet brickwork thousands of pottery goblets or by a facing of baked brick set in bitumen. The ziggurat had a series of steps leading to the upper terraces and finally to the summit, where there was a small temple of whitewashed brick and imported timber, adorned in silver, lead, copper, and lapis lazuli.

The great ziggurat of Ur, with a tower about 800 ft. (240 m.) high, may have inspired the legend of the Tower of Babel. The lower stages were black, representing the underworld; the top stage was red, representing the hospitable earth; the shrine itself was covered with blue-glazed tile, representing the heavens; and the roof was gilded, representing the sun. This architectural masterpiece had a number of constructional refinements: the vertical lines were slightly convex to offset an optical illusion by which they would otherwise appear concave, and the floor plan had

A ZIGGURAT (AS RESTORED)

slightly convex sides for the same purpose. The Tigris-Euphrates culture used this principle 20 centuries before the Greeks, to whom it has been commonly attributed. (See further UR; PRE-HELLENIC ARCHITECTURE: Mesopotamia.)

**3. City Walls.**—All the cities of the Tigris-Euphrates culture had city walls from their beginnings and continued to maintain and add to them. Some built walls of incredible size and strength, such as the famous walls of Babylon, built during the reign of Nebuchadnezzar (605 to 562 B.C.). Today they are in ruins, having been used as brick quarries in both ancient and modern times. Many of the irrigation dams across the Euphrates today are built entirely of bricks taken from these walls.

Originally there was an outer and an inner wall surrounding the entire city. The outer wall was double, its outer part 24 ft. (7.3 m.) thick and built of burned bricks 13 by 13 by 3 in. (33 by 33 by 8 cm.) laid in bitumen. The inner part was of unburned brick, 36 ft. (11 m.) from the outer, with the space in between filled with dirt to produce an elevated road on which several chariots could ride abreast. The inner part was also 24 ft. (7 m.) wide and had towers every 150 ft. (46 m.). The total outer wall was then about 84 ft. (26 m.) thick. Its height is not known, but it was at least double the thickness, or about 175 ft. (63 m.) high. The inside wall was also double, and its entire width was 55 ft. (17 m.), and its height probably 120 ft. (37 m.).

These walls were only the defenses of the city itself. Nebuchadrezzar's palace had additional walls: the first wall, of burned brick, was 20 ft. (6 m.) thick and 60 ft. (18 m.) high; the second, third, fourth, and fifth were each higher than the others and had defense towers. The sixth wall was as high as some of the tallest modern buildings. The Ishtar gateway leading to the palace was covered with blue-glazed brick and large reliefs showing bulls, lions, and dragons in white, blue, yellow, and black. The royal records also speak of great bronze gates.

**4. Irrigation and Flood Control.**—Although there was a need for a centrally planned irrigation system in the Tigris-Euphrates Valley, there were so many small city-states constantly at war that there was no centrally built, maintained, and controlled system of irrigation canals and basins. Nonetheless, irrigation was extensive and on the whole effective.

There was a main canal conducting the waters of the Tigris through the plains to Ur on the lower Euphrates. Another went to the north of the Tigris and was carried by an aqueduct over a smaller river. A great dam was built on the Euphrates to irrigate the area around Babylon. The characteristics of the Tigris and Euphrates produced a system of irrigation different from that possible on the Nile, and one that was more difficult. Both the Tigris and the Euphrates rise suddenly and irregularly between April and June and bring down in their headlong rush a tremendous amount of silt. Because this water came too late for winter crops and too early for spring crops, it was necessary to expend a tremendous amount of labour to build storage basins and to keep them and the feeder canals free of silt, but the water once stored could be used when desired. These people could thus harvest three crops every two years. Additional heavy labour was required for works to control destructive floods.

In the Tigris-Euphrates cultures the engineer was able to undertake large-scale works because there was a wealthy, strong central government sanctioning expenditure of a substantial economic surplus on defense, on religious structures, and on irrigation and flood control. The engineer himself was a priest or a palace official and so had access to power and the necessary capital. Good engineering is evident in the extensive use he made of local material, and his construction methods also made effective use of cheap slave labour. Although little refinement or skill was required in this construction, there were impressive achievements.

## B. THE NILE VALLEY

The ancient Egyptians inhabited an area different in many important respects from that of the Tigris-Euphrates. Consequently the technologies that arose in these two places were very different. The Nile Valley stretches in a long narrow strip, in some places only a few miles wide, and in no place, except in the delta, much more than 30 mi. (48 km.) wide. Because this area was extremely fertile, it attracted people from very early times. Geographically it was well protected, and very little external defense was needed.

The Nile created no overwhelming engineering problems. It flooded gently, regularly, and predictably from August to October, just in time for seeding winter or spring crops. Although it brought down from the mountains a rich silt adequate for renewing the land, there was not so much as to silt up irrigation canals quickly. Only dikes and basins were needed to spread the water over the fields while its rich silt settled out. The water could then be drained off by opening dikes lower down the river.

About 2000 B.C. the Egyptians added to this basin irrigation a system of canals, dams, and reservoirs, which permitted irrigation of areas not amenable to the basin system and which also made possible year-round irrigation. While irrigation was necessary to Egypt and involved much labour, it was far easier than that required in the Tigris-Euphrates Valley.

The Nile flows peacefully and slowly from the First Cataract at Aswan to the Mediterranean and provides a broad channel for easy transportation. The flooding of the Nile also was the means by which the Egyptians could easily transport heavy weights, such as building stones, because these could be moved onto barges when the Nile was low and carried down to their destination at the flood, and the cargo could be removed when the river receded.

The Nile Valley was also favourably endowed with raw materials. Egypt was far less dependent on imports than were the Tigris-Euphrates cultures. There was a local supply of good flint; stone tools were therefore used by Egyptian farmers long after the Tigris-Euphrates people used bronze. Except for timber Egyptian imports were almost entirely luxury items. Limestone was quarried at Tura and Masara, and the whole area had an abundance of good building stone, such as granite, basalt, diorite, and quartzite. Furthermore, all these materials were either on the surface or could be worked by tunneling into the cliff faces, and all were available for easy transportation by river.

**1. Egyptian Civilization.**—Almost from the beginning of the Urban Revolution the Nile Valley formed a more natural economic unit than did the Tigris-Euphrates Valley. A centralized government appeared very early, and power came under the control of the palace rather than the temple, so that the accumulation of economic surplus was in the hands of the monarch and not the priests.

Egyptian religious beliefs generated much of their engineering activity. Their religion was strongly materialistic, yet the Egyptian gods were believed to sit in moral judgment on the soul of the individual after death. The Egyptian believed that the body would literally rise again from the grave. In addition, the many souls of the Egyptian had to return to the body at intervals. It was thus essential for the body to be preserved, not only because it would be necessary for the resurrection but also for the peace of the souls until the final resurrection should come. These beliefs accounted for embalming, pyramids, and cliff tombs.

The engineer held a high position in Egyptian society. He was commonly an army officer, a priest, or a member of the nobility, and sometimes even a member of the royal family.

Industry was rather limited, but there was an enormous agricultural surplus. Egyptian commerce included a substantial Nile trade, as well as trade with Crete, India, and with the Tigris-Euphrates Valley. Much of the commerce was in precious materials, but it also included other items, such as timber.

Much of this trade was carried by private merchant ships, which were protected by the navy. Though similar to merchant ships in construction, with hulls built of small pieces of wood jointed together and given lateral rigidity by thwarts and longitudinal strength by means of a hogging frame (there was no internal rib frame), navy ships were not as high in the ends and had wooden bulwarks to protect the rowers and raised platforms for the archers and grapnels. Ramses II (c. 1304–1237 B.C.) had 400 vessels on the Arabian Gulf, some having an overall length of 488 ft. (149 m.). Fleets of this sort need not surprise us, because as early as 3500 B.C. the Egyptians had sailboats and other boats built of planks, and by 3000 B.C. Egyptian sailing ships were freely navigating the eastern Mediterranean.

The Egyptian economy was based upon agriculture. The fertile soil of the delta needed only to be scratched, the seeds sown, and the harvest was bountiful. Thus the plow received little development in ancient Egypt. The upper lands were tilled with a simple wooden plow having metal points, two handles, and a pole attached to a yoke of oxen. No reins were used; usually a man other than the plowman guided the oxen with a short stick.

The arts and crafts of the Egyptian economy were nonetheless important, particularly for local supply. They were carried on almost entirely in small shops, much as they are today. Weaving at a high level was done, and even the finest modern weaving is not as perfect as the best of the Egyptians. Rich cloth was embroidered in gold thread, and patterned weaving was also done. Excellent leather work was common. The cabinetmakers produced the finest furniture, much of it inlaid with ebony and ivory. The jewelers worked in gold inlaid with precious stones; silver and gold services were produced, and their vases were the artistic equal of any the Greeks produced later. Metalworking was outstanding, principally in copper and bronze. The Egyptian craftsman knew smelting, forging, soldering, alloying, inlaying, engraving, and gilding. The metalworkers were, for instance, able to produce a good copper pipe, 1,300 ft. (396 m.) of which was found in one of the temples.

The wheel was used by the potters, who had good clay to work with. They also glazed their pottery in blue, green, yellow, and red, and even were able to glaze cut stone and to glaze over writing. The Egyptians did beautiful enameling, particularly on gold. They worked in glass, producing mosaics, bottles, and beads with writing on them. The gemworker worked on quartz, using a jeweled or flint point because bronze was not hard enough. Alabaster vases survive which were cut out with tubular drills of copper, with sand or perhaps emery as the cutting medium. Imitation pearls, amethysts, and emeralds made by the sophisticated Egyptians fooled the rather gullible Greek tourists of later times.

Thus the Egyptian material culture was that of a highly refined people, skilled in the arts of peaceful living yet able to defend themselves. The army was used in peace principally as a skilled engineering labour force, though there was also a considerable supply of unskilled (usually nonslave) labour available for irrigation projects and construction of temples, pyramids, tombs, and obelisks. The Egyptians had no need for great walls, bridges, or river embankments, although they had far better materials to work with than did the Mesopotamians.

**2. Pyramids.**—Though from early times the Egyptians had had buildings of rough stone blocks and had cut and dressed the hardest rocks, the most outstanding feature of their pyramids and temples is the sudden perfection of stone masonry—a measure of the rise of Egyptian culture under the influence of the Urban Revolution. When the Egyptians found the suitable form of the pyramid and temple and the easily worked stone of their quarries, there was a rapid development. In fact, from the combination of the art form and these techniques grew what was to be the basic nature of Egyptian engineering construction: gigantic buildings, designed to be durable and characterized by grandeur and extreme accuracy of work, in at least some of their features (*see further EGYPTIAN ARCHITECTURE*).

The rocks from which these buildings were constructed, principally limestone and sandstone, were quarried systematically, utilizing only tools of copper and bronze. The extremely heavy stones were generally transported from the quarries to the site of the

THIS DRAWING SHOWS HOW THE GREAT PYRAMID OF KHUFU (CHEOPS) AT GIZA MAY HAVE BEEN CONSTRUCTED WITHOUT CRANES, PULLEYS, OR MECHANICAL TACKLE. THE STONES FOR THE PROJECT TOTALLED 2,300,000 AND AVERAGED 2.5 TONS EACH

pyramid by boat, utilizing the Nile. Hatshepsut's barge, for example, carried two obelisks 97.5 ft. (30 m.) long and weighing 350 tons each.

The Egyptians handled stone blocks without any lifting tackle, and recent studies conclude that they did not use rollers either. The basic tools were the lever and the ramp, plus high concentrations of unskilled labour. The temples and pyramids were probably built stage by stage, the stones, according to most authoritative opinion, being hauled up along dirt ramps, probably on sledges, and slid into place.

The pyramid was built of a core of blocks of nummulitic limestone fitted rather loosely into place, and this core was covered by an outer casing of blocks of fine limestone fitted very precisely one to the other. Close joints, less than  $\frac{1}{8}$  of an inch, were made by fitting the blocks together before they were put in place, the dressing being done very carefully to get an exact fit. The outer faces of the pyramid were dressed after the pyramid was completed.

The magnitude of these finished structures and the precision with which they were constructed is impressive. The Great Pyramid at Giza contains approximately 89,000,000 cu.ft. (2,518,000 cu.m.) of stone, and the area of the base is about 13 ac. (5 ha.). When the casing blocks were in place the base was 752 ft. (230

m.) square, and the pyramid was probably just under 500 ft. (150 m.) in height. It consisted of about 2,300,000 blocks, each weighing an average of about 2½ tons and arranged in some 210 layers, the total weight being just under 5,000,000 tons. The base is an exact plane very nearly horizontal, but tilted slightly from the northwest to the southeast corner by about half an inch. The dimensions of the sides are very closely equal; the difference is only 1 part in 5,000. The corners are right angles to within a maximum error of 3.5', and the sides are oriented north, east, south, and west to within a maximum error of 5.5'. (*See PYRAMID.*)

BARGE TRANSPORTATION OF QUEEN HATSHEPSUT'S OBELISKS DOWN THE NILE RIVER. THIS SCENE IS RESTORED FROM A RELIEF ON THE WALL OF THE QUEEN'S TEMPLE AT THEBES

ERECTION OF AN OBELISK: (TOP TO BOTTOM) OBELISK HAULED UP RAMP BY SLEDGE; PARTIAL REMOVAL OF SLEDGE WITH ALL LASHINGS REMOVED; OBELISK EASED INTO SURROUNDING SAND; OBELISK DRAWN UPRIGHT ON ITS PEDESTAL

**3. Obelisks.**—Egyptian obelisks were large slender stones erected as religious symbols within the courtyards of the temples. Great numbers of these of various sizes appeared throughout later Egyptian history. Still in place in a quarry at Aswan is an obelisk that was intended to be 137 ft. (42 m.) tall, with a base 13.75 ft. (4.19 m.) square, and tapering slightly to the pyramidion at the top. Made of hard red Aswan granite, the obelisk weighs about 1,168 tons. The Egyptians could probably have gotten it out of the quarry in about six months, but work was abandoned when a crack was discovered. The available evidence and engineering calculations indicate that obelisks were erected using ramps, a sledge, and a brick-lined hole filled with dry sand which was carefully removed to let the obelisk down exactly onto the prepared base. See OBELISK.

### III. GREEK AND HELLENISTIC CULTURES

The mainland of Greece is broken into a number of small valleys by a series of steep mountains. It was in these valleys and in a few fertile plains that classical civilization grew. For geographical reasons alone it was impossible for any Greek city-state to attain the wealth, power, or centralization possible in the Nile Valley.

**1. Early Greek Technology.**—The Greek states remained relatively small units throughout their history, and their economic capacities were extremely limited. Although iron tools

HISTORICAL PICTURES SERVICE

ANCIENT GREEK SHIPS. PADDLE-SHAPED RUDDER, HELD TO THE SHIP'S SIDE, WAS WORKED BY A THWARTSHIP TILLER

were available, as well as a supply of excellent raw materials, such as limestone, marble, and good wood for building, Greek society looked upon the man who worked with his hands as somewhat inferior and not far above the status of a high-class slave. Thus, labour was in relatively limited supply, and most of it was slave.

The religion of the Greeks led them to construct temples which were also public buildings. In contrast to Egyptian beliefs, Greek ideas of life after death were vague, and there was little concern for tombs.

Many of the small cities were far from a water supply, and it was necessary to construct rather primitive aqueducts. Certain city-states, of which the most outstanding were Corinth and Athens, undertook commerce and overseas trade, but this was generally of a coastal nature. Their principal peacetime engineering efforts were then in building temples, aqueducts, and ships. Greek engineering was always on a small scale, and since it did not involve complex problems, primitive methods were usually satisfactory. From an engineering standpoint, the classical Greeks were not impressive.

Greek technology involved the working, in a primitive way, of iron, a metal that had been very scarce in earlier periods. The Greeks had a number of technical devices, such as the wine press, based upon such simple devices as the lever. Weaving was known to them, but it was distinctly inferior to Egyptian work. Although

the states were almost continuously at war with one another, this did not result in major defensive works for their cities.

**2. Greek Ships and Buildings.**—Because of their need for defensive sea power, the early Greeks did contribute to the development of ships. The Homeric ship had a keel, a sternpost, a stempost, ribs, and outside planking fastened with treenails. It was carvel-built (*i.e.*, the planks were flush at the seams) as compared with the clinker-built (overlapping) construction of the northern Vikings, and the keel was fully developed to give longitudinal strength. This type of construction was unknown in Egypt and northern Europe for many centuries. The Homeric ship was a long narrow vessel, whereas the Egyptian ship was quite broad and much larger. Estimated to have been not more than 125 ft. (38 m.) long and with a capacity of about 50 men, the Homeric ships had a forecastle partly decked over, a ram bow, and apparently a small poop with a high curving sternpost. A raised gangway ran the entire length. The construction was probably quite light, because the ships often broke up upon ramming. As in Egyptian ships the mast was lowered by a forestay, but the Homeric ships had shrouds and a square sail that permitted them to sail before the wind. A most important contribution of Homeric shipbuilders was the keel; the Egyptians had only the hogging frame. The Homeric ships were also low in the waist, since they had to be rowed, except before the wind. Later there were oar holes and built-up sides, with one man to an oar. By 250 B.C. some of the Greek ships had lead sheathing.

Despite their artistic achievements as architects, the classical Greeks were not remarkable structural engineers. The Greek builder, working with soft stone and iron tools, used rectangular blocks of a size easily lifted into place by a gang of men, without attempting to get a precise fit, since he set them in mortar. Like the Babylonians and the Egyptians, the Greeks were acquainted with the arch, but they too used it only rarely. Their principal form of construction was the temple, which consisted only of walls, columns, and a simple roof. Because the Greeks had substantial timber available, it was possible for their roofs to span a considerable distance, but these roofs transmitted both a downward and an outward thrust upon the supporting walls or columns. As a result the Greeks needed heavy walls and colonnades to take up the side thrust.

Although the effects of their contributions to engineering were not felt for a long time, the development of mathematics and the science of mechanics by the Greeks laid the foundation for the beginning of engineering as an applied science.

**3. Hellenistic (Alexandrian) Engineers.**—With the death of Alexander the Great (323 B.C.), his vast empire collapsed, and there arose in the eastern Mediterranean a number of cultures that were at least partial inheritors of the world of classical Greece. One of the most interesting was that centred around the city of Alexandria. This Hellenistic society flourished from approximately 300 B.C. to A.D. 300 and was of considerable technological importance. (*See HELLENISTIC AGE.*) It was a mixture of various peoples and cultures, polyglot in religion, in language, and in social and economic customs, but united by trading and manufacturing cities of great wealth. There was, however, no strong central government to control the wealth and no priesthood to control the economic surplus. It was therefore not possible to undertake large-scale engineering operations. Despite these limitations this society

A NORIA USED TO RAISE WATER TO A HIGHER LEVEL

made important contributions to the advance of technology. Their engineers confined themselves to small-scale devices, but had the advantage of the classical Greek development of, and interest in, the theory of mechanics.

From this period survive the earliest names of engineers and books about technology. Four men especially worthy of mention are: Hero of Alexandria, Ctesibius, Philo of Byzantium, and Vitruvius. Vitruvius was, to be sure, a Roman, but he based most of his celebrated treatise, *De architectura*, upon Alexandrian sources. These men, who lived between 300 B.C. and the early years of the Christian era, used a number of mechanical devices. The lever had been used in its simplest form for prying by both the Egyptians and the Tigris-Euphrates peoples. It was used in a

HISTORICAL PICTURES SERVICE  
A WELL SWEEP, USING THE PRINCIPLE OF THE LEVER TO RAISE WATER

water-raising device, called the well sweep, in Egypt as early as 1500 B.C., and it is still so used in this area. The lever may also have been used in warfare to lift men over walls, and legend has it that Archimedes used it to lift ships at the siege of Syracuse. There is no evidence of the use of the pulley and windlass in the Tigris-Euphrates Valley, Egypt, or Greece, but they were in use at Alexandria by the beginning of the Christian era. Wedges and inclined planes were known from the very earliest times, but the screw made its appearance in the Hellenistic world for oil and wine presses and as a water screw. There were also cranes having from one to four masts, which combined the principles of the lever, the pulley, and the windlass. Descriptions survive of pulley blocks, and there were directions on how to calculate the mechanical advantage of different types of windlasses. These mechanisms were sometimes operated from the power of a treadmill.

Alexandrian engineers used mechanical equipment for raising water. The water screw, traditionally ascribed to Archimedes, may have been invented in Egypt, but Vitruvius wrote that it was used to clear mines, to pump out the holds of ships, and for irrigation. The *noria*, described by Vitruvius, was also used to raise water. This was an undershot waterwheel having pots for lifting water on its circumference. It might have been as much as 30 or 40 ft. (9 or 12 m.) in diameter. In theory, the *noria* was driven by the current of the stream, but sometimes it had to be assisted by a treadmill.

Alexandrian engineers were skilled in constructing mechanisms for warfare. The bow and the sling had developed in Neolithic times; of the two the bow is more important technologically. To increase its strength, mechanisms were developed to draw and hold it in readiness. Extra flexion was obtained by separating the single bow into two arms. Hero described extensions of this crossbow principle to throw a very long arrow and heavy balls. This device, the *ballista*, was probably invented about 400 B.C. and improved by Ctesibius. It had a range of about 300–400 yd. (270–370 m.).

Ctesibius and Philo both described the force pump, which served as a domestic water pump and as a fire engine. The Alexandrian engineers also pumped air, and as early as the 2nd century B.C. a water organ may have been used. One of these was described as having been driven by a windmill. If the description is trustworthy, this is quite remarkable because the windmill did not appear again as a source of power until about A.D. 300 in Persia. The windmill organ apparently

BROWN BROTHERS  
RECONSTRUCTION OF A WATER CLOCK  
FROM VITRUVIUS' DESCRIPTION

of millet or mustard seed escaping slowly through a hole. There were also lamps with automatic feed of the wick and oil; these involved clever gearing and an understanding of pneumatics and hydraulics.

These small devices provided Alexandrian engineers with invaluable experience with mechanical elements, especially lever systems, gears, and pulleys.

The Alexandrian engineers also concentrated on instruments of precision for measuring angles and time. These instruments played an important part in the history of mechanical devices and were early examples of precision instruments that were to become critical appendages in the development of astronomy and modern engineering. Most important of those for measuring time were water clocks (see *CLEPSYDRA*). Later editors of Vitruvius' works added to their books illustrations upon Renaissance designs, but scholars have reconstructed a water clock to fit Vitruvius' description. In the water clock two critical problems were solved: (1) how to get uniform flow of water; and (2) how to convert a uniform time motion into the solar time then in use.

The Alexandrians used the cyclometer to measure distances for surveying. This was one of the earliest applications of a chain of gears, but gears also used to move heavy weights were described by Hero. Vitruvius described a flour mill employing gearing—unique because gearing was generally used for transmission of motion, not for transmission of power.

had a trip-hammer action, a device which was not to appear again until the Middle Ages.

The most generally exploited sources of power were slaves. Although animals supplied a further source, they were used rather inefficiently. The high cost of feed in a relatively dry climate also served to discourage the use of animal power. Since human muscular power was adequate for most purposes, Alexandrian engineers directed their talents in other directions, especially in the development of instruments of precision and curious little amusement devices.

**4. Mechanical and Precision Devices.**—Ingenious mechanisms, intended to produce motion while using a minimum of power, were nearly all weight driven. For example, there were puppet theatres in which a fire was lighted, girl figures came out and danced, the Bacchus inside turned and poured libations, a winged Victory turned on the top, and the entire display ran up and down a track. Power was provided by a lead weight falling under the control of a quantity

THE DIOPTRA

One instrument, the dioptra, was developed by Hero into a precision instrument for surveying. Originally an astronomical instrument, Hero converted it into a transit, and from this invention he advanced a new theory of surveying. Little is known of earlier Egyptian surveying techniques, except that the results were accurate. The Greeks measured horizontal angles at  $90^\circ$  with the groma, or surveying star, and measured slope fairly well by the chorobates, a crude device about 20 ft. (6 m.) long with plumb bobs and a water level. These devices had been used as early as the 7th century B.C. in tunneling from both ends for a distance of 550 yd. (500 m.). Hero's dioptra, however, was a major step forward, for, except for a telescope and compass, it had all the features of the modern transit. He gave a full description of it and its use in his treatise on surveying.

**5. Milling Grain.**—A number of other appliances that appeared for the first time in this era were not mentioned in engineering treatises, probably because they were considered too commonplace or because the authors, under the influence of classical theories of mechanics, did not consider them machines. One was a device for milling grain. Early methods had been simply to pound with pestle and mortar or to use the saddle quern, but, with the increase in weight of the implements, the work of grinding grain ceased being women's work and instead became the work of male slaves. The earliest certain reference to the quern was made by Cato (234–149 B.C.), who described a rotary mill turned by two asses, but wrote that it was also sometimes turned by two male slaves. Great querns, turned by men or horses, have been found in large numbers in Pompeii. The weight of the upper stone was

a technical revolution that was eventually fulfilled during the Middle Ages in the West.

#### IV. ROMAN CULTURE AND TECHNOLOGY

The Roman political, social, and economic organization required a different kind of technology. Even though the Romans had a strong central state with great political and financial power, there was considerable autonomy of local government. The Romans undertook a regulated and orderly expansion of the public services required by the rise of cities and their high population density. Though calculating and materialistic, the Romans had a broad tolerance of many religious groups. In the architectural and building arts their aim was primarily utilitarian. They were not greatly concerned with the construction of great temples, monumental graves, or even walls for defense. Instead they built palaces, baths, amphitheatres, granaries, bridges, roads, aqueducts, and drainage canals. Public institutions and buildings had a political function and were an integral part of the Roman political organization. The practical means by which the Romans maintained their power were prosperity, law, the army, order, and the display of prestige and power.

The needs of government required a number of contributions from engineering. Because communication was necessary to maintain the strong bureaucratic centralization of this vast and far-flung empire, roads, writing, and the Latin language had to be spread abroad. Efficient utilization of labour and building materials, especially stone and concrete, was needed to construct great aqueducts supplying water to the large populations in the cities and to build the great public buildings, the most magnificent of the world of antiquity.

Roman organizational skill was especially important in the use of labour in extensive engineering projects. Workmen's associations, united by religious and economic bonds but sharply distinguished by trade, guarded the construction traditions passed from generation to generation and from experienced workmen to apprentices. Similarly, organizations of architects and engineers provided training and status. Although aristocrats

were taken into these training schools, men from the ranks were accepted as well. In addition to these associations there was another group of professional corporations, the contractors. In large undertakings such as masonry construction, this group controlled the mass of unskilled labour for the state and undertook the planning, execution, and responsibility for the project.

This organization of labour and skill produced a sharp division between the crafts, so that they became almost independent of one another. For example, one association constructed the solid brick or concrete walls, another applied the marble facing. This specialization, however, did not prevent a slow but sure advance of engineering knowledge gained by empirical means.

**1. Architecture and Engineering.**—The separation of the craftsman and the architect from the building engineer meant that connection between the aesthetic elements and the constructional elements in Roman architecture was lost. Compared with the organic nature of Greek, Egyptian, and Babylonian architecture, Roman architecture had a certain inherent contradiction. The result was an independent evolution of the technical building methods, as opposed to their architectural and decorative features, which were derived from Alexandrian Greece. As an art that had completed its cycle, Alexandrian architecture was not rejuvenated by the Romans. Hybrid and lacking in constructive spirit, its rapid decay climaxed in excessive ornateness and poor execution.

At the same time, however, the technical aspect of Roman building made progress. The construction associations valued cumulative experience and progressive improvement made primarily by

QUERNS EXCAVATED FROM POMPEII

carried by a spindle fitted in the lower stone. There were holes through which the grain passed down, and the stone was turned by wooden bars. The use of asses in turning these querns was probably one of the earliest applications of animal power to industrial work.

**6. The Impact of Hellenistic Technology.**—The concern of Hellenistic engineers with the study and control of motion, both in theory and in sophisticated mechanisms, proved most significant, and the fundamental theories worked out for them proved adequate for many centuries. They included the theory of mechanical advantage of the five simple machines (the lever, the wheel and axle, the pulley, the wedge, and the screw), as well as the theory of the elementary principles of hydrostatics. Furthermore, the Alexandrian engineers had all the elementary motion chains: the screw, the wheel, the cam, the ratchet, the pulley, and the gear. The crank was known, but not the crank chain which we call the treadle. The development of animal and nonmuscular power, which was to come later, arose out of the change in scale in engineering work rather than in new principles.

The Alexandrian period was therefore highly important in the history of technology. Its actual engineering achievements seem meagre in comparison with those of the Tigris-Euphrates and Egyptian cultures and with those of the Roman culture, which was partially contemporaneous with it, but it marks an important transition from the engineering of cultures based upon man and his hand tools to cultures exploiting animals and mechanisms. The achievements of the Hellenistic engineers marked the beginning of

practical discoveries. While most of their techniques were jealously guarded and handed down in symbolic written form, these groups were prepared to take advantage of new discoveries. The result was that the 3rd and 4th centuries A.D. saw both decadence in Roman architecture as an art form, e.g., in marble ornamentation, and, at the same time, some of the empire's greatest triumphs in building construction, as in the extension of the principles and techniques of the arch and the vault to the dome. The building art was still full of constructive spirit toward the end of the empire, but it declined because political uncertainty caused the collapse of public and private prosperity, and no further building on a large or costly scale could be undertaken. Thus today many Roman buildings, because they have lost their marble ornamentation, are better architecturally than they were in Roman times. Building construction preserved the simplicity, dignity, and strength of the republic, while Roman art and architecture showed the influence of the luxury, decadence, and weakness of the empire.

Since the goals of building construction were to represent the importance, the impressiveness, and the grandeur of Rome, the organic feature of this architecture was vast, covered, and open spaces in harmony with each other. The principal constructional problem faced by the Roman engineer was how to span large enclosed spaces far too great for the wooden construction of the Greeks and for the stone construction of the Egyptians. The solution was twofold: (1) an entirely new structural form, or at least an entirely new development of a structural form, the arch and the vault; and (2) the development and use of materials, especially brick and concrete, in new ways.

The arch had been timidly attempted by the Egyptians and the Babylonians and it was known to the classical Greeks. It was used systematically, though on a rather small scale, in Etruscan bridges and tombs from the 7th century B.C. From this Etruscan origin the arch and the vault were improved slowly but steadily to greater and greater size until their constructional possibilities were highly developed by the Romans.

When the arch was used to span great distances, as the Romans did, new problems arose. Other peoples had spanned great widths within the limits of available timber, as did the Greeks; or they had found it necessary to divide the rooms by intermediate columns in the Egyptian manner. The Roman engineer had to face two very difficult problems: first, the efficient construction of walls, arches, and vaults (a problem for the mason); second, and, far more difficult, the design of arches and vaults in combinations so that the lateral thrusts would be balanced against each other insofar as possible and any residual thrusts carried to the ground. Both problems were, however, closely bound together in producing a building architecturally able to span wide spaces yet with good illumination and proper balance, while constructionally providing a highly stable building that would be able to defy time with a minimum of upkeep.

**2. Building Construction.—Walls.**—The Romans used widely divergent methods of constructing building walls at different times and places, but everywhere they based their building on the advantageous use of local materials and skills. In the East, in Greece, and in Asia Minor, Syria, and North Africa, where there were skilled masons and good supplies of stone suitable for squaring, the Romans used substantial blocks of cut stone. In central Italy they continued the Etruscan type of squared masonry stone, with the stone used either as solid masonry or as a facing. The typical Roman edifice or structural wall was, however, a sort of concrete set in molds that were sometimes temporary or sometimes an integral part of the wall.

In walls of cut stone the courses were of uniform thickness. The blocks were parallelepiped in shape, with the width equal to the height and both equal to either one-half or one-third of the length. (All the dimensions were multiples of linear units of measurement.) In ashlar (facing and core) the stones for facing the outside wall were alternately either headers or stretchers. In every case the stones were bonded; that is, the square end of some were laid to the front face so that the stones of the face were bonded back into the core. The headers, which served to bond the facing to the core, sometimes had curves at their inner end

A CONSTRUCTION VIEW OF A ROMAN WALL, SHOWING THE PLACEMENT OF THE STRETCHERS (PARALLEL TO FACE OF WALL) AND THE METHOD OF BONDING THE HEADERS TO THE CORE

to reinforce the hold of the bond. In walls of this sort the core was either concrete or layers of tamped random rubble.

Walls of concrete masonry were most characteristic of Roman methods, particularly in Italy and in the western regions of the empire. They usually consisted of a facing, commonly of burned brick, which served as a mold and was put into place by skilled masons. Then the *caementum* was put into place by unskilled labour overseen by the masons. This was not usually of concrete in the ordinary sense, but was constructed of alternate layers of stone and gravel mixed in place with a very thin cement. The facing bricks, of uniform sizes, were laid with mortar joints of less than one-third of an inch. In the course of time there was a gradual increase in the thickness of Roman bricks to approximately 2 in. (5 cm.), and in joints there was some slow increase in size. These variations in no way were detrimental to the solidity of the Roman cement-brick wall. This was due to the excellent quality of the cements and to the close union between the facing and the core through the use of bonding.

Roman methods of wall building survived long into the Middle Ages and were used by Byzantine and Western builders. Though they built good solid walls for their great public buildings, this was not always true in private dwellings. At the time of the republic Rome was built largely of unburned brick, although burned bricks were also used. Augustus' boast that he found Rome a city of brick and left it a city of stone is clearly an exaggeration, but he was not far from a point. In the empire these unburned bricks were used for private or everyday uses in much the same way that they had been used in Egypt, Greece, and Babylonia.

**Arches.**—To make possible the Roman goal in building construction, the Romans used the arch, the vault, and the dome. The full true arch was used widely, e.g., over doors, for bridges, and for sewers. Sometimes it was the free arch, full or segmental, and sometimes it was the arch bonded to the materials above it. Thus the characteristic form of Roman building construction was rows of arches supported on piers, and arches which supported the vault or dome structure above them.

Arches were made of a number of different kinds of material, one of the most important being concrete-brick, in which the brick was commonly embedded in concrete work. When exceptional strength or great resisting power was called for, the Romans frequently used double or even triple ribs of bricks to form their arch. Usually the arch was constructed of large bricks about 2 ft. square, the ribs filled later with concrete. Sometimes the arch of brick was shown in the outside facework; at other times these ribs were inside the concrete. These ribs had several functions: first, to control internal stresses in the concrete; second, to determine the line of thrust; and third, to prevent deflection. Relieving arches were sometimes built into walls in order to give them stability and sometimes to locate stresses at given points on foundations provided only at these points. (See ARCH AND VAULT.)

**Vaults and Domes.**—Growing out of the arch, in order to span large enclosed spaces, was the vault. This basic characteristic of Roman building, and a Roman invention, occurred in three principal forms: the barrel vault over a rectangular area; the groined or cross vault, i.e., the intersection of two vaults; and the dome set over a circular or polygonal base. The typical Roman vault construction was of concrete, formed by centring to give a complete semicircle. As with the arch, brick ribs distributed the main stresses. This method of construction was both rapid and economical, but it required centring to sustain the tremendous weight until the concrete set, although the brick ribs put in place first could take much of the load.

Any sinking or inequality in the foundations would result in undistributed stresses and cracking. One solution was to use elaborate foundations, which were far more substantial than those deemed necessary today. Another was to distribute the load of vaults through ribs and piers to the foundation. This principle was long the basis of Romanesque and Gothic vaulting. The basic principle, then, was not to use massive brick or concrete arches but rather a kind of hollow brick caisson penetrated by cast concrete.

**The Internal Balance of Forces.**—The most important characteristic of the Roman vaulted buildings, and the greatest contribution of the Romans to building methods, was the organic structure of the whole. All the elements—the wall, the arch, the simple or groined vault, and the dome—were manifestations of a single idea. The Roman vaulted building achieved a perfect balance of all its parts, in both construction and design, in an arrangement that provided for counterbalancing the thrusts of the heavy superstructure. This principle, which was strictly Roman, represented an enormous advance over anything that had previously been done in building construction. It was even a greater contribution to the building art than either the arch or the vault. In effect it consisted of equilibrium based upon the elimination of the thrusts by mutual oppositions and by transferring all the residual thrusts to the outside walls. The question then was how to take up the final thrust. Sometimes this was done with external buttresses, which were later used extensively in Gothic architecture, but more commonly internal buttresses were used. Sometimes an internal buttress on a lower portion became an external buttress for an upper portion. This system, which became the basic principle of later church construction, could be very complex, as seen in the Baths of Diocletian, one of the most magnificent ancient buildings and one of the best engineering designs. It is also apparent in the Baths of Constantine and the Temple of Minerva, where the side portions serve as buttresses for the main portion. From these Roman forms also came the basic structure of Byzantine architecture, particularly the dome.

**Construction Tools and Techniques.**—Centring was common and inclined planes were used. The Romans had no particular problems of lifting, for the blocks of stone were relatively small and the pulley and the multiple purchase were available. They sometimes used cranes—in fact, cranes of the same type were used in parts of France and Italy as late as 1900. Rapid construction was one of the most typical, most important, and perhaps the most fully developed of the Roman technological achievements.

**3. Aqueducts.**—The Roman aqueduct was one of the most characteristic of all Roman structures (see **AQUEDUCT**). It was used to carry large quantities of water to the great cities of the Roman Empire for drinking, public and private baths,

fountains, and irrigation, and it even supplied some country villas along the way. The aim was to collect the water from springs and rivers and to convey it partly by tunnels and partly by channels supported on walls and arches to a reservoir outside of the city, from which it was distributed. With few exceptions, the great aqueduct was an open channel (i.e., without pressure). Since it depended on gravity flow, it had to avoid an adverse slope and sudden changes of gradient that would produce too sudden a change of speed. The entire channel, therefore, had to be kept above the level of the reservoir at some height across the plains that commonly surrounded the Roman cities. Thus Roman engineers often had to take long detours to get a favourable gradient. This was sometimes done with great precision, but often crudely.

Roman aqueducts were better building structures than they were hydraulic systems. The tunnels were sometimes 2 mi. (3 km.) long. When channels were set on top of long masonry structures that crossed over valleys and plains, one aqueduct was sometimes superimposed on another to save masonry. The Romans apparently had difficulty in making the channel permanently watertight, for it required continual repair and reconstruction. This problem was described in detail by Sextus Julius Frontinus in his book *De aquis urbis Romae* when he was superintendent of aqueducts in A.D. 97. The problem was considerable, for in those times the city of Rome had a supply of about 38,000,000 gal. per day. Rome's water was supplied by about 9 aqueducts, whereas in the Middle Ages the city simply used the waters of the Tiber.

The Romans on rare occasions used a siphon system with adverse gradients. The pipes were of terra cotta or wood, sometimes of metal or lead, and usually embedded in masonry. This type of aqueduct was not often used near Rome because of its small capacity, but it was used elsewhere. However, the principal use of hydraulic flow in pressure tubes was in distribution from the reservoirs. This was accomplished by lead pipes and a system of taps and valves.

The reservoirs were connected directly to the aqueduct systems. Some reservoirs were as large as 21,600 sq. ft. (2,000 sq. m.), but their construction was quite simple. No large arches or vaults were used; instead, a rectangular space was divided at regular intervals by a series of light arcades that supported the covers. These arcades were commonly connected by barrel vaults, and doors were provided for shutting off parts of the reservoir for cleaning. The outside walls, which were subjected to lateral pressure, were usually supported by earth embankments or sometimes by external masonry buttresses. The inside walls were covered with cement.

DEUTSCHEN MUSEUMS, MÜNCHEN

PAINTING BY ZENO DIEMER OF A NETWORK OF ROMAN AQUEDUCTS, SHOWING SECTION UNDERGOING REPAIRS

mill embodied the primary characteristics of the modern mill. The mill had found numerous applications, many of which required new devices and mechanisms for specialized power transmission. These adaptations were often as complex as the

POST WINDMILL WITH GRINDING MACHINERY IN MILL HOUSING, WHICH WAS ROTATED INTO WIND BY LIFTING BRACING AT REAR OF MILL AND PULLING IT AROUND BY TAIL POST. ILLUSTRATION FROM AGOSTINO RAMELLI'S "LI DIVERSE ET ARTIFICIOSE MACHINE," 1588

basic mill design. By the 16th century printed books with woodcuts showed many such machine elements that could be traced back to the Middle Ages. Among these were the cam and tappet, the windlass, gear trains, the crank, the bow spring, the treadle, and the flywheel.

**Applications of Mill Power.**—The mill was most widely used for grinding grain, but its utilization for other tasks had a considerable impact upon society.

One important application was the use of water mills for fulling cloth, a finishing process that provides more body and greater resistance to wear by compressing, shrinking, and binding the fibres more closely together. Before the 13th century, cloth to be full was immersed in a tub or trough of water, and fuller's earth was added as a degreasing agent. Then the cloth was pressed or trampled by foot or hand. But the water mill for fulling consisted of a trough and two wooden hammers that worked alternately by tappets or cams on a drum fixed to the shaft of a waterwheel. Fulling mills, which were also used for felting unwoven fibres, enjoyed widespread use in Britain and resulted in a shift of the textile trade from the urban centres of the eastern lowlands to the country districts of the north and west where there were fast-running streams suitable for water power.

The water mill replaced human muscle power in other endeavours. During the first decades of the 13th century waterwheels were used at the silver mines in the Alpine region of Trent and the South Tirol, and in the 14th century the water mill became fairly common in all Alpine regions. The mill then spread into the copper and silver mining districts of Germany. The great waterwheel powered the hammers used for crushing the ore and for forging the wrought iron, and it moved the bellows supplying the blast to raise furnace temperatures. In the 16th century waterwheels were used extensively to raise water by pumps from flooded mine shafts.

From the 12th century water power came to be used by malt mills, wood-turning mills, mills for grinding pigments, grinding mills for cutlery, paper mills, and silk-twisting mills.

**3. Clocks.**—The invention and perfection of the mechanical clock introduced new elements of first importance for an industrial technology: the refinement of mechanical design; an impressive facility in the use of geared wheels and other precision mechanisms; and development of the principles of applied mechanisms. The water clock, known in ancient Egypt, was further developed by the Alexandrian engineers of the early Christian era. Its basic principles remained essentially the same until the 13th century, but the complexity of its mechanisms increased. Along with the water clock, the sun dial and the sand glass were used for measuring time. All three of these devices lasted long after the appearance of the mechanical clock, surviving through the 18th century in a modified form because they were cheaper, reasonably accurate, and easier to repair.

The Alexandrian engineers designed water clocks in combination with various puppet devices in which the hours were sounded by a reed and trumpet or by a ball falling on a bronze gong. The puppet show was sometimes quite complex and involved devices for showing the phases of various heavenly bodies. A few of these water-clock puppet shows were apparently built in Europe, but most were sent as gifts to various Christian monarchs from the Muslim world, an example of the diffusion of technology from the Muslims to the Christian world during the Middle Ages.

The time-measuring device of the water clock was water that was allowed to flow out at a controlled rate through a small orifice. The motion was transmitted from a float by means of weights, cords, rollers, and pulleys, which in turn controlled and moved a bewildering variety of symbols and figures giving astronomical data, the hours of the day, and ingenious displays.

Both falling weights and gears—two fundamental elements of a mechanical clock—were used in the puppet shows of Alexandria but the problem of obtaining regular weight-fall had to be solved in order to invent an accurate mechanical clock. The critical invention of the mechanical clock, therefore, was the escapement.

Until 1344 there was no mechanical clock movement whose general characteristics can be analyzed in detail. Many early references exist, but they are all doubtful or clearly refer to water clocks or astronomical devices. A clock erected in 1344 at the entrance tower of the Carrara Palace in Padua by either Jacopo de' Dondi or his son Giovanni is the first identifiable mechanical clock. It had a falling weight as the source of power, a mechanical escapement and a balance wheel to control the fall of this weight, and gearing to transmit the motion to signal the hours. Several other mechanical clocks were built about this time in Italy but the first authenticated one outside of Italy appeared in Strasbourg in 1352.

The mechanical invention that controlled the falling weight was the verge escapement, which included a balance wheel or a foliot (crossbar) balance (see CLOCK). These escapements solved the problem of accelerating weight-fall by stopping the movement of the clock at regular intervals. The escapement of a clock built for the Palais de Justice in Paris by Henri de Vick between 1364 and 1370 had a foliot balance rather than a balance wheel. It also had a 500-lb. (225 kg.) falling weight and a 1,500-lb. (680 kg.) weight connected to the striking-train mechanism. These heavy weights were necessary because of the great friction and interference between the parts of the crude blacksmith-forged mechanism.

Much improvement was required in the mechanical clock from these crude, large, and heavy devices: first, in the design of the gears; and second, in the design and construction of the foliot balance and escapement. De Vick, for example, had a brilliant conception of a mechanism, but what was necessary was refinement of design. Even with refinement, the clockmaker was held back by poor techniques of construction and by the lack of precision tools and skill. Thus, De Vick's clock stood at the close of the primary development of the mechanical clock, yet at the beginning of a long process of refinement in mechanical concepts. No changes in the basic mechanism were to occur until the introduction of the pendulum in the second half of the 17th century.

## VI. THE FLOWERING OF EUROPEAN TECHNOLOGY

Since the Middle Ages Western man has thought of nature as a great complex of energy and matter to be utilized for his own benefit. In fact there has been a cumulative character and a continuity of development in the West extending from the Roman era—a continuity defying division into eras and epochs. Of particular importance in this respect were the outstanding inventions and achievements of the Italian architect-engineers, the German metallurgists and printers, and the Dutch construction engineers from the 15th to the early 17th century.

**1. Canal Construction.**—Bertola da Novate (c. 1410–75), one of Europe's outstanding civil-hydraulic engineers, proposed new and improved canals to strengthen Milan economically. First he improved the existing canal system to the northwest, which had carried the cathedral stones to Milan from the quarries near Lake Maggiore and which had become known as the Naviglio Grande. Bertola then built a canal from Abbiate, on the Naviglio Grande, to Bereguardo, a village to the southwest near the Ticino River, where it became navigable for boats destined for the important trading centre of Pavia and the Po River. The Bereguardo Canal, completed in 1458, was about 12 mi. (15 km.) long and had the first complete set of canal locks—one of the major inventions in civil engineering history.

The mitred canal gate, which improved the San Marco lock in the northeastern part of Milan, was probably invented by Leonardo da Vinci. The lock made possible the interconnection, formerly prevented by their different levels, of the Martesana Canal and the Naviglio Grande. Earlier canal lock gates had been vertical gates raised by a windlass (similar to the portcullis of the medieval castle) or single gates swinging on vertical axes. Leonardo's San Marco lock (c. 1500) was of masonry. Its gates of wood were reinforced by iron straps at the joints and by iron hinges. A pair of gates swung together at a mitred joint to prevent water leakage. The twin-mitred gates angled into the downward force of the stream, and thus the force had a component carrying the strain into the masonry wall. Because the gates could not be opened against a head of water, small hinged doors or 'skets' near the bottom admitted water into a lock before the gate was opened. Thus the pressure on each side of the gate was equalized before chains pulled the gates against the side walls of the lock.

The San Marco lock survived into the 20th century much as Leonardo designed it.

**2. Improved Production Techniques.**—Upon completion of the canal systems, Milan's industry and trade flourished. Entrepreneurs and craftsmen increased production by introducing in-

genious techniques for mass production, some of which were described by Vannoccio Biringuccio (1480–c. 1539), author of the influential work on metallurgy, *Pirotechnia*. He observed that one brass foundry in Milan could furnish all of Italy with its products. It employed eight masters and helpers in one room who did nothing but form molds in loam for the object manufactured on that particular day. Among the objects made at the shop were harness buckles, cups, belt buckles, chain links, bells, window fastenings, and thimbles. Other craftsmen specialized in hammering brass tinsel, filing thimbles, and turning candlesticks. This system made possible the extensive marketing of brass objects through lower production costs.

Milan's neighbouring city-state, Venice, had another remarkable industrial enterprise,

the naval arsenal, where galleys were constructed and armed. In the 15th century the arsenal used effective production techniques and an assembly line to make the famous Venetian galleys that maintained the Mediterranean trade of the city. Because in both the 15th and 16th centuries the Turks challenged the naval power of the Venetians, a large fleet of military galleys was of critical importance.

A typical Mediterranean galley of 1500 was about 120 ft. (37 m.) long and had a 15-ft. (5-m.) beam. Construction was of wood, with planking laid over the keel and ribs carvel fashion (edge to edge). The galley carried about 150 oarsmen, each with a great 120-lb. oar, but with a favourable wind a lateen, or triangular sail, could be used. Forward was a cannon and small gun and a ramp that could be used for boarding after contact with an enemy vessel.

LEONARDO DA VINCI'S SKETCHES FOR HIS CANAL AND LOCK SYSTEM

The arsenal maintained a reserve fleet of as many as 100 unassembled galleys. The numbered parts of each reserve galley were stored in the arsenal yard and warehouses, and parts of the same type for different galleys were stored together. This system saved space and avoided the weathering that assembled galleys would have suffered.

**3. The Work of Leonardo da Vinci and Albrecht Dürer.**—In considering Leonardo's engineering work, we are primarily concerned with the extensive compilations of his notes and drawings. His notebooks, begun in 1488, were typical of those of a practising engineer. Except for a treatise on the flight of birds and one on hydraulics, these notes were never worked into a systematic treatise. The rest of the notebooks were roughly organized material for treatises that could have been written on human anatomy, the anatomy of the horse, motion, impacts, weights, moments of force, and the elements of machinery. If they had been systematically organized, they would have rivaled all other treatises of the 16th century.

Leonardo was especially interested in mechanisms and military engineering, although his notes on elements of machinery were the most complete. There were drawings for a whole series of mills: water, wind, horse, tread, and crank, as well as a series of drawings concerned with pumps and hydraulic apparatus of all types, many of them clearly designed to be driven by power. The sketches showed not only general features but also the details of the parts. There were also fairly detailed sets of drawings on textile machinery, on the manufacture of metallic parts, and on artillery. Some of the sketches were those of existing equipment; others were attempts to apply known principles to the solution of problems. Still others were clearly original ideas. Among his original ideas were industrial appliances invented for profit (his needle-polishing machine) or for fame (his flying machine).

Leonardo took the most important step of separating the study of mechanisms from the general study of machinery. Earlier engineers and many of Leonardo's successors considered every machine as unique and consisting of parts peculiar to it. They had no concept of a mechanism: a mill was a mill; a stamp was a stamp. Thus generalized concepts were lacking, and the approach was empirical. But Leonardo's works manifested generalized concepts, e.g., his means for transmitting and converting the form of motion.

His notebooks exhibited a number of mechanisms for the conversion of rotary motion to various kinds of reciprocating motion and for converting swinging motion to rotary by means of ratchets.

Leonardo also had the modern engineer's interest in the reduction of friction. He sketched the use of antifriction rollers and designed a pulley block in which he approached more nearly the ideal of a complete roller bearing. He made various applications of this principle, which he called the "wonder of the mechanical art."

One of his most intense engineering interests was in various types of automatic machinery, an outstanding example being his machine for cutting files. In this machine he applied to industrial machinery a falling weight as a source of power. He also made drawings of screw-thread cutting devices having practical application. Such machines would have made possible the economical production of bronze and iron screws, which came into general use in the 16th century. Earlier screws were cast and then finished by hand with the file, or smaller screws were cut directly from the metal with a file. Leonardo's screw cutter had three spindles mounted on the machine frame. The outside spindles acted as lead screws moving the frame through which they passed and in which they worked in nuts. The screw was cut on the centre spindle. The operator powered the machine by a crank and could change drive gears to vary the pitch of the screw being cut.

Leonardo made many drawings of metalworking devices, including a series for shaping iron by rolls and drawing frames. These had been known since the 12th century for light work, but Leonardo was the first to propose their use in heavy work and to drive them by power. Actually not until the 18th century were rolling mills extensively used, because there were problems of power, details of heavy construction, and unknown properties of the metals at various temperatures.

Albrecht Dürer (1471-1528), the Leonardo of the north, wanted to do for Germany what the Italian architect-engineers had done for their homeland. Dürer planned an ideal town, considering social conveniences as well as problems of defense. The foundations were situated in the southern corner so that prevailing winds carried noxious fumes away from the town castle. Another section was the site of church activities. The town hall, together with its square and fountain, and the nearby marketplace formed a communal centre. The copper-smiths, molders, and turners lived near the foundry, and bakers, butchers, and brewers occupied the food quarter. Some streets were reserved entirely for craftsmen.

**4. German Metallurgy.**—The Fugger family of Augsburg was heavily involved in silver and copper extraction and processing in Hungary and in the Alpine province of the Tirol. Jakob Fugger, "the Rich," became head of the family enterprises in the 1490s and formed a partnership with the mining engineer Johannes Thurzo, who agreed to improve mines and smelters in return for a part of the resulting savings. The Fugger-Thurzo Trading Company's silver and copper mines, smelters, and mills in Hungary, in combination with the growing investment in copper and silver properties in the Tirol, allowed the family to dominate the European market. In 1495 Thurzo built a large smelter at Neusohl in Upper Hungary to smelt the area's silver-rich copper ore. The copper was man-

PAGES OF MECHANICAL SKETCHES FROM AMONG THE MANY SCIENTIFIC STUDIES CONTAINED IN LEONARDO DA VINCI'S NOTEBOOKS

keted as sheets, plates, and other forms, while much of the silver went into government mints.

The newly invented liquation method was used to extract silver from copper ore. In the process, crude argentiferous copper was melted with lead in a small blast furnace and cast in cakes in copper molds. In the next step, the liquation process itself, the cakes of copper-lead-silver were heated on the hearth with charcoal at a temperature above the melting point of lead and below that of copper, thus allowing the more fusible lead to be drained off, carrying with it the silver, which was chemically attracted to the lead. The copper (the spent liquation cake) was then further refined for marketing, but the liquated lead and silver had to be separated. Using cupellation (a process known from antiquity), the lead-silver was melted on the hearth with charcoal and bone ash, and an air blast was directed on the surface of the melt to oxidize the lead. The lead oxide (litharge) was run over the rim of the furnace; that remaining was combined with the bone ash deposited on the hearth, and the silver was collected in a pocket at the bottom of the hearth.

Improved chemical techniques, along with the utilization of natural power and machines, increased the output of nonferrous metals. Fast-flowing mountain streams powered the heavy waterwheels that drove the furnace bellows and activated the heavy trip-hammers at the forge. Waterwheels also powered crushing machines and operated pumps that drained the mines and made possible deeper shafts. *De re metallica*, a treatise on mining by the

German engineer Georgius Agricola (1494–1555), has remarkably descriptive woodcuts showing the various machines at work. Specific machine elements included gear trains, flywheels, windlasses, cranks, fans, bellows, cams and tappets, treadles, chain-and-ball pumps, bucket pumps, and suction pumps. Impressive mechanical systems included water mill hoists, crushing mills, and windmill-powered ventilation fans.

The technique of casting, especially in bronze, had been known to antiquity, and by the 16th century casting in both brass and bronze was common. Molds for large bronze and brass casting were of loam, while lead and tin for pewter were commonly cast in molds of soft stone, metal, and sand or clay. Sheet lead was cast for roofing and for the siding of ships by pouring lead down an inclined sanded plane. Not until about 1615 were lead sheets rolled for these purposes. Precious metals were also cast and then die stamped for coins.

**5. Assaying.**—In the 16th century no field of metallurgy was more advanced than that of assaying. It was the technical means by which certain economic and financial questions could be answered before the capitalist invested in a mining or metallurgical enterprise. The assayer also determined the quality of coinage, which had long troubled the economy.

The complex assay technique involved special furnaces, utensils, weights, balances, and fluxes. Though the basic concern of the assayer was quantitative analyses of ores and metals, he also resorted to qualitative assaying by observing the colour of the flame and smoke and by use of the bead test (using glass rather than borax). His principal handicap was lack of precise furnace control and means of measuring temperature.

The empirical knowledge of the 16th-century assayer remains impressive against a 20th-century background. Assayers knew, for example, of the depression of the melting point in alloys and of the proportions for minimum melting point in alloys. Knowing that certain molten metals did not mix, they were able to separate two liquid metals, as in liquation. They recognized the existence of terminal and intermediate solid solutions, the formation of inter-metallic compounds, the process of hardening by cold working and of annealing to produce softening, and the changes in properties resulting from transformation or from solubility changes. They also knew of different affinities of metals for each other and for nonmetals (this was in fact the principal means of assaying and refining). They were aware of metals replacing each other from solutions of their salts and of diffusion in the solid state of metals (this was used in making steel, cementing gold, and blanching silver). The relationships between the structure and the properties of metals, as well as fracture tests, were used to determine quality and as a guide for composition and for heat treatment.

An important step taken during the 17th century was the application, made in 1664 by Henry Power, of the microscope to the study of fracture structure. It was also discovered that sparks struck from steel would provide a rough gauge of its properties. Density measurements had been made as early as the 11th and 12th centuries, and in the 17th century lists of densities of metals and alloys became extensive and even systematic. The limited information obtained from tests of metal strength may have been of some use to engineers, but assaying techniques were not used in an organized way to serve the engineer and builder until the 18th century.

No general theory of metals was really possible until the second quarter of the 19th century, when chemical theory, atomic theory, and the theory of crystalline structure were being formulated. However, the economically important and technically refined practice of assaying produced factual information and accurate numerical data from which the scientist later formulated hypotheses and generalizations. Fortunately the assayers were literate men as a result of their responsibility for keeping accounts of precious metals and their close contacts with highly placed persons in state and private enterprise. Thus they were able to organize and record their empirical information about copper, lead, and precious metals. This was not the case with the ironmaster dealing in a comparatively crude bulk product. Not until the 18th century was there a study devoted exclusively to iron by R. A. F. de Réaumur.

A WOODCUT ILLUSTRATION SHOWING 16TH-CENTURY MINING OPERATION: FROM "DE RE METALLICA" BY GEORGIUS AGRICOLA

HISTORICAL PICTURES SERVICE

A 16TH-CENTURY ASSAYING ROOM, AS ILLUSTRATED BY LAZARUS ERCKER

The outstanding 16th-century books on metallurgy by Vannoccio Biringuccio, Georgius Agricola, and Lazarus Ercker all discussed assaying in addition to a general discussion of metallurgy.

The lag in scientific treatment of metallurgical data did not prevent the assayer from proving his worth to the miner and smelter as well as to the master of the mint. Ercker wrote in the dedication of his treatise that he intended it to be useful in developing the rich metal and mineral resources of the Holy Roman Empire by both imperial and private enterprise. Ercker believed that God had put metals and minerals in the earth to be obtained, converted, and employed by man in his labours. Therefore, with the help of God and through complete information (supplied by Ercker), he believed these resources would be further developed and long maintained.

**6. Printing.**—The invention of printing with movable cast type is an outstanding example of the increased sophistication, complexity, and precision of technology in the early modern era. Its history throws light upon the actual process of complex inventions.

The invention of printing is also an example of the epoch-making effect of technical change on the diffusion of knowledge, particularly technical knowledge. Once the fundamental breakthrough occurred in printing, improvement and refinement followed rapidly. In a decade, printing developed from the crude type forms of the earliest text printed between 1444 and 1447 (the "Fragment of the World Judgement") to the masterly printed 42-line Bible of about 1453.

The invention of printing is of interest as one of the first instances of substitution of mechanical devices for hand work in order to obtain accuracy and refinement of execution, as well as reduced cost. Furthermore, printing was one of the first examples of mass production of a standardized product. Also noteworthy is the fact that the print shop from the beginning was characterized by capitalistic methods; it was from the outset a factory rather than a craft shop.

Printing with movable cast type was not a simple invention; it was the bringing together of a number of earlier inventions. The invention of paper was an absolute prerequisite to printing, since parchment and papyrus were completely unsuitable. Parchment was difficult to handle, irregular in thickness, costly, and in limited supply; papyrus was hard and brittle. Linen paper, which was suitable, had been invented in central China at the close of the 1st century A.D. It spread rapidly in China, reaching the West in the mid-12th century through the Islamic world.

Other prerequisites were ink and the press. Early wood-block printers used thin distempers, which were soon replaced by boiled oil. The cloth and wine press was modified for printing by applying a quick-acting screw, by the means of holding the paper and type to prevent twisting, and by devices to give uniform pressure of the plate.

Another prerequisite was a metal suitable for type casting. In the 17th century lead-based alloys were common, but the first of the 15th century was probably a tin-based alloy of the kind used by pewterers.

The printing problems of the 15th century centred around engraving and casting. They required for their solution a number of minor inventions to which two distinct crafts, the wood engraver and the goldsmith, contributed. The goldsmith had already become familiar with dies, punches, and delicate methods of casting in connection with the manufacture of coins and jewelry. The wood engraver had a long history as a printer, using single-block illustrations. Although the historical order of occurrence is uncertain, it is clear that wood-engraved prints were known in 1410, wood-engraved prints with engraved text by 1437, and wood-engraved books with printed text and illustrations about 1440.

*The Role of Gutenberg.*—Johann Gutenberg (c. 1398–1468) is generally credited with the next great step forward. The more moderate Gutenberg supporters accept the passage in the *Chronicle of Cologne* of 1499 naming Gutenberg as the inventor of printing at Mainz but allow a "prefiguration" in Holland of printing with movable type. Gutenberg's more dogmatic followers insist that the Dutch books were all block-printed pages and not from movable type. Probably the Dutch technique anticipated the German (Gutenberg) method and even inspired it, but it is equally clear that the German work later surpassed it.

The city records of Avignon, France, for the years 1444–46 refer to Procopius Waldvogel (Waldvogel) of Prague who registered agreements to teach the art of the goldsmith and of writing mechanically. In July 1444 he agreed to deliver "2 alphabets of steel, 2 iron forms, a vise or screw, 48 forms of tin, and various other items pertaining to the art of writing." Another contract refers to "27 Hebrew characters, 48 letters engraved on iron, and

HISTORICAL PICTURES SERVICE

A PRINTING PRESS OF 1520, FROM A CONTEMPORARY WOODCUT ILLUSTRATION

uments for writing mechanically in Latin." Here, then, is evidence of hard metal punches and type molds. There is, by contrast, no evidence for the use of hard metal punches by the Dutch or by the Germans this early. No evidence of printing survives at Avignon, however. Thus it is clear that various lines of development were leading toward perfecting printing with movable type through wood engraving, metal engraving, and metal casting.

Gutenberg, Johann Fust, and Peter Schoeffer were associated in an enterprise connected with printing in Mainz from 1450 to 1455. One of them, or the group, made important contributions to the printing process. It is fairly certain that Fust was the financier. Possibly the technical genius was Schoeffer, because there was a marked improvement in a psalter printed by Fust and Schoeffer after they had separated from Gutenberg. However, the outstanding products of the Mainz group can be dated by an almanac of about 1448 and the famous 42-line Bible of about 1453. Gutenberg, then, was associated with an effort that produced the most impressive early works in modern printing.

The precise chronology of invention of printing cannot be determined on the basis of historical evidence, but logic provides a list of problems solved in the invention of a system of printing with movable cast type. These were the selection of a suitable metal for casting, the design of an adjustable metal type mold, and stamping with a hard punch the letter-forming matrix.

The first type cast by Gutenberg was probably of pewterer's metal and in a metal mold. (The first molds were not adjustable, but a distinct mold was used for each different size matrix, e.g., m and w; o and s; i and j; and so on.) A steel punch, like those used by the goldsmith or coin minter, probably impressed the matrix with the letter form. The type in final form was a slender rod of rectangular cross section usually about an inch long, with the letter formed at one end. The typesetter fixed the type in page forms that made up the face of the press. From 2 to 16 pages were placed in the press to be printed on a single sheet of paper. The critical invention that made type available in quantity also permitted technical excellence in printing was the adjustable type mold with a lead or copper matrix.

The resulting 42-line Bible was far ahead of the best manuscripts in quality, and the best books became objects of luxury, not simply cheap substitutions for manuscripts. As a matter of fact, cheap books were not available for some time. There were many professional copiers who, at low pay and for years after the development of printing, could turn out manuscript copies of small books less expensively than the printer. (See further PRINTING.)

**7. Dutch Dikes, Drainage, and Windmills.**—Much as German printing and metallurgy were outstanding during the 16th century, when Germany enjoyed an era of economic and political prominence, Dutch engineering was impressive in the late 16th and early 17th centuries, when the northern Netherlands won independence and commercial power. The Dutch engineers were especially noted, then as now, for winning land from the ocean and inland seas.

The skill and heroic achievements of the Dutch engineers have inspired admiration, for between 1540 and 1690 they reclaimed about 440,000 ac. (178,000 ha.) from the ocean and inland seas. By the end of the 15th century the Dutch had developed effective dike techniques. In Friesland, where the sea was strong, raised earth cores plastered with clay that was strengthened by reeds or straw, along with palisades of piles. Centralized administration of large projects furthered the activity.

More complex was the reclaiming of rich lands from great inland lakes and seas. This activity in the formation of polders (enclosed reclaimed land) involved surrounding drowned land by a dike, digging a network of drainage ditches or canals within the polder, erecting drainage pumps, and constructing exterior canals to carry the pumped water off to main drainage canals or the sea.

During the 16th century the windmill-driven scoop wheel for drainage became common. These mills lifted the water up and out of the polder. There were also windmill-driven screw pumps.

Simon Stevin (1548–1620), one of Europe's great engineers, described drainage mills of advanced designs in an outstanding treatise on the principles and practice of drainage-mill use and construction.

## VII. ORIGINS OF THE BRITISH INDUSTRIAL REVOLUTION

### A. IRON, COAL, AND STEAM

In the 17th and 18th centuries iron, coal, and steam played increasingly significant roles and contributed greatly to the transformation of society through an industrial revolution (q.v.).

**1. Increased Iron Consumption.**—During the Middle Ages the price of iron had remained fairly stable despite the steady rise of wages and the price of raw materials, but in the 16th century, even with technical improvements such as larger smelting units and better machines for producing the furnace blast by water power, the increased cost of labour and particularly of fuel led to higher prices for iron. However, the consumption of iron rose steadily. In the early 16th century about 60,000 tons per year were produced in western Europe, approximately half of it in Germany and about a fifth in France. Frequent wars, mechanization of the armament industry, increasing use of iron castings, the use of cast iron in the production of wrought iron, and the need for kitchenware and simple tools and utensils contributed to increased demand.

Changing standards for heavy artillery produced new requirements in the quantity and size of iron castings. For larger cannon, as many as four blast furnaces had to be used. Musket balls were cast, but Biringuccio stated that the best were forged in dies. Iron cannon balls were cast in split molds.

**2. Smelting Improvements.**—The market demand and fuel shortages brought responses from inventors and engineers, especially in Britain. One solution was an increase in furnace size, which, along with an increased air supply, led to higher furnace temperatures, higher yield, and higher efficiency. Thus, while in 1600 an average blast furnace could produce about 1½ tons of pig iron a day, by 1700 about 2½ tons of pig iron per day were produced from less than 3 tons of charcoal.

The medieval furnaces had been less than 10 ft. (3 m.) high and used natural draft or foot-operated bellows. Since the furnace temperatures were not high enough to melt the reduced iron, it dropped as a spongy mass to the bottom of the furnace. This "bloom" of iron was removed from the furnace, leaving nonferrous matter as slag. The bloom was then reheated and hammered to remove the slag.

During the 14th century the furnace for smelting iron underwent fundamental changes. The *stückerföfen*, a German invention, may have resulted from increased furnace heights (as high as 30 ft.) and stronger air blasts (bellows driven by a waterwheel). Early in the century it was found that iron collecting at the bottom of the furnace was liquid and that the liquid could be run free for casting. The hotter furnace melted the iron, and it also kept the descending iron longer in contact with glowing charcoal. This increased the carbon content of the iron, lowered its melting point, and further facilitated the production of liquid, rather than bloom, iron.

The liquid iron was cast into molds near the furnace tap as "pigs." If the cast pigs were to be made into wrought iron, they were carried to the forge, which was often equipped with waterwheel-powered bellow furnaces and hammers. In the furnaces the excess carbon was burned off and the metal heated for forging. By the 17th century waterwheel-operated rollers shaped large cross-section blooms from the forge into bars.

As the blast furnace spread throughout Europe in the 15th century, the availability of cast iron increased its consumption. There was also an increase in iron production resulting from the development of a continuous process in which ore and fuel were added at the top of the furnace and the iron tapped at the bottom. A longer operating cycle was also possible before it was necessary to reline and repair the furnace. In 1400 in England the smelting process could not be continued longer than 6 days; by 1600 in Germany it lasted as long as 24 days; and by 1700 in England the

blast furnace could be operated continuously for about 40 weeks.

Mechanization became common in working iron. Power-driven tilt hammers appeared in the 16th century, as did power wire drawing, rolling, and slitting mills. The furnaces, however, were usually fed by men or animals without the help of machinery.

As the use of the blast furnace and cast iron increased in the 16th and 17th centuries, a number of problems developed. A bewildering variety of iron came from the furnaces, and its behaviour varied accordingly. Variations in ferrous materials were thought to be due to variations in furnace conditions, and not until the 18th century was the role of carbon in iron recognized, since slight modifications in temperature could produce substantial variations in the amount and state of carbon content.

The next 150 years were to make iron and steel the most important engineering materials. This did not occur, however, until the pressing problem of fuel shortage was solved by the substitution of coal for charcoal.

**3. Increased Consumption of Coal.**—In late medieval Europe, coal in the Low Countries was mined on a limited scale. In the first half of the 16th century the output of these mines increased three to four times to provide fuel for the growing manufacture of iron and other metals along the Meuse River. But the greatest development occurred in Great Britain, where by 1675 more than 2,000,000 tons of coal per year were produced, amounting to five times the production of the rest of the world.

This shift from a wood-burning to a coal-burning economy raised problems in three important areas: first, in the industrial use of coal, especially in smelting iron; second, in mining coal; and third, in transportation.

By 1603 the price of wood from Britain's depleted forests was so high as to be prohibitive for many industries. Some industries, such as wine, alum, or brick manufacturing, easily shifted from wood or charcoal to coal. But for other industries a shift of this sort required the invention of new methods. For instance, the glassmakers found that, in switching from charcoal to coal, the coal fumes darkened the glass.

The problem of charcoal shortage led the iron industry to move nearer the surviving forests, but this also meant farther away from markets and sometimes from the ore. The problem of replacing charcoal had to be solved in several of the ironmasters' processes: smelting iron from ore in the furnace; the production of wrought iron from pig iron at the forge; and in working wrought iron into manufactured goods. In each instance the products of coal combustion could damage the material.

Smelting was the most difficult problem because the iron ore had to remain at high temperatures in order to be reduced and carbonized into cast iron. The solution came from a remote field: the production of beer. In drying malt for beer, charcoal had been used, but in order to reduce the price some brewmaster decided to use coal. The effect of the fumes on the taste of the beer was abominable. The idea occurred to someone that the more noxious fumes could be driven from coal by heating it, *i.e.*, by converting it to coke. After a number of attempts from 1640–50, the British brewmasters eventually succeeded in substituting coke for charcoal. Yet it was not until 1709 that Abraham Darby successfully applied coke to blast-furnace smelting.

Abraham Darby I (1677–1717) and his son established an iron-making dynasty, and their works at Coalbrookdale became the leading centre of metallurgical progress. Darby also introduced a coal-fired reverberatory furnace for remelting cast, or pig, iron; and his son contributed a system, involving careful ore selection, which allowed refining coke-smelted cast iron into bar, or wrought, iron at the forge furnaces. As a result of the Darbys' work the market for cast-iron products (pots, kettles, furnaces, and so on) increased, especially after a technique for thin casting in dry sand molds was developed by the father.

The Darbys pioneered in other metallurgical techniques as well. In order to use coke economically, the furnaces at Coalbrookdale had to be enlarged so that the iron ore could remain in contact with the coke longer, and the temperature had to be increased by a more powerful air blast.

Although Henry Cort (1740–1800) is credited with the invention

of the puddling technique for making wrought iron without charcoal, he is better remembered as the inventor of a system of converting pig or cast iron into wrought iron without charcoal and in quantity. Cort's puddling process, described in his patents of 1783–84, utilized a coal-burning reverberatory furnace and a rolling mill. It involved heating the pig iron in the hearth of the furnace where the fuel did not come in contact with the iron, but the heat passed from the furnace and over the adjacent hearth. With a chimney supplying an air draft, no bellows were used. The carbon in the most exposed melt combined with oxygen from the air, and the relatively carbon-free portions of iron, whose melting point rose as a result, became stiffer and were removed by the ironworker in large globs. Impurities were then hammered out, and the wrought iron blooms were shaped under the forge hammer.

Cort completed his system by passing his forged bars or plates through V-grooved rolls that not only further shaped (elongated, the wrought iron into rods but also pressed out earthy particles, cinder, and impurities. The good quality and quantity of malleable iron made possible by Cort's system strengthened the British economy on the eve of the French Revolutionary and the Napoleonic Wars. Malleable iron found use where cast iron could not function, *e.g.*, in anchors and many ship fittings.

The increased demand for coal, which began in the 16th century and intensified in the 18th, raised problems of finance and of mechanization and power, of draining the mines as miners moved deeper after exhausting surface veins. The value of coal was too low to allow the use of horse mills, which were economical in mining gold and silver. Since water power was not always available, there was a need not only for improved pumps but also for a new source of power to drive them. The solution was found in the steam engine, the history of which began with the need for pumps.

**4. Development of Pumps and Power Sources.**—Agricola illustrated his 16th-century *De re metallica* with many examples of pumps. Among these was a chain of dippers powered by a man through reduction gears, or by animal and water mills. Agricola also depicted suction pumps, force pumps, and a "rag and chain" system used in central European mines. Each type had limitations: nature restricted the suction pumps; the force pumps overstressed the pipes, which were usually wooden; and the "rag and chain" system put a heavy load on the power source. These pumps could remove water from depths of several hundred feet, but this required an elaborate mechanical system involving overly large waterwheels or a series of pumps at different levels, with the accompanying problem of power transmission or location. Limited underground space discouraged the use of pumps in relays.

The increase in size of towns also produced a greater demand for centralized water supply and for pumping units. Though the Roman solution had been to use aqueducts with gravity feed, European cities in the 16th and 17th centuries used pumps operated by waterwheels or windmills (the English city of Gloucester had such a windmill water supply in 1542). By 1526 Toledo, Spain, had a complex apparatus built by an Italian engineer, Juan de Turriano, and in 1548 Augsburg had a water supply provided by mechanical power. Other German towns soon followed suit. In 1582 London pumped its water supply, as did Paris in 1608. Throughout the 17th century, city waterworks became common. Since great volumes of water were moved, large but inefficient sets of pumps and waterwheels were used.

Other circumstances defined the need for new power sources. Windmills and water mills not only were large for the delivered horsepower but they had limitations imposed by geography and the climate. The locations of towns and heavy industry before the steam age demonstrated their dependence upon the fall line of rivers. While in freezing weather these towns and industries would lose this valuable power source, summer might bring a paralyzing drought. Some ironworks were limited to less than two months of operation because of climatic conditions. Labour problems and high capital costs per unit resulted from idle machinery. Prevailing winds made windmills economical in some areas, but without potential in others. Nevertheless, areas with water and wind power were frequently the cradles of economic development. The

WATERWHEELS DRIVEN BY THE FORCE OF THE RIVER CURRENT ACTIVATE A SYSTEM OF PUMPS TO PROVIDE AN IN-LAND WATER SUPPLY. FROM JACOB LEUPOLD'S "THEATRUM MACHINARUM HYDRAULICARUM," 1724-25

need for a reliable, low-cost, concentrated, and widely available source of power for industry was obvious, but the drainage of mines was the most pressing problem and was the immediate cause of the development of the steam engine.

**5. Early Steam Engines.**—The earliest steam prime movers, which functioned without the pistons and cylinders of later engines, used air pressure working against a vacuum, and some used the force of steam pressure as well (see STEAM). Edward Somerset, 2nd marquess of Worcester (1601-67), built what was probably the first steam device capable of economically significant work. Though the design of his water-commanding engine is uncertain, it probably resembled that of Thomas Savery, patented in 1698.

Savery's engine had a vessel with stopcocks for admitting steam from a boiler. A stopcock-controlled supply of cooling water from a tank above was directed over the hot surface of the steam vessel. Self-regulating valves admitted water from below to the steam vessel or out of the vessel to a higher discharge level. In operation, the hand-controlled stopcock was opened to admit steam into the steam vessel, then this was closed, and the stopcock controlling the cooling water from the elevated tank was opened to run over the steam vessel, condensing the steam and creating a vacuum. A valve in the pump pipe then opened automatically as atmospheric pressure at the base of the pump pipe forced water into the vacuum. Next, the steam was admitted again into the nearly water-filled vessel to force the water up through pipe outlets.

Savery's engine found application in at least one mine and several water-supply installations. He clearly demonstrated the possibility of using air and steam pressure in a pump, but his device had to be located within 20 ft. (6 m.) of the water level at the bottom of the mine. This meant that the draft from the fire helped to ventilate the mine, but if the pumping device failed and the mine flooded there would be no means of clearing it. Furthermore, the device could not push water up to the top of a deep mine because the permissible boiler pressure was limited to

less than 8-10 atm. The device had no safety valve to prevent explosions, and it required about 20 times more coal than a modern engine.

The next major innovation in steam-engine design was the introduction of the piston and cylinder. Otto von Guericke (1602-86) had shown the potential of air pressure moving a piston against a vacuum, and Christiaan Huygens (1629-95), the Dutch scientist, and his assistant Denis Papin (1647-c. 1712) had experimented with gunpowder explosions and steam to create a vacuum beneath a piston. Papin recognized the economic significance of the atmospheric engine, but it was an Englishman, Thomas Newcomen, who invented the first industrially significant piston-and-cylinder steam engine.

**6. Newcomen's Atmospheric Engine.**—Little is known of Newcomen's career, though his letters to Robert Hooke of the Royal Society indicated an interest in developing pump pistons. Sometime after Savery's patent of 1698, Newcomen, Savery, and John Cawley joined forces. The first working atmospheric engine of Newcomen and his associates was built at Wolverhampton, Eng., in 1712. At first Newcomen used surface condensation on his engines, but faulty operation suggested the advantages of internal jet condensation.

In Newcomen's engine the piston was lifted by a counterweight on the pump side, and steam flowed into the piston cylinder under very low pressure. When the steam was condensed by the cooling water to form a vacuum, the piston was pushed down by atmospheric pressure working against this vacuum. Since the steam had only enough pressure to flow in and clear the cylinder of the water of condensation, no work was done by steam pressure.

A challenging problem was to design a mechanism to operate the various cocks and valves automatically. An engraving of 1719 shows the solution: a plug tree for operating the cocks and valves. This was Newcomen's invention, despite anecdotes of his lazy and ingenious "tap boy" Humphrey Potter conceiving of the device to save his manual efforts.

In the larger Newcomen engines it was necessary to use large

OTTO VON GUERICKE'S DRAMATIC DEMONSTRATION OF THE PRESSURE OF THE ATMOSPHERE MOVING A PISTON INTO A VACUUM. THE MAN AT THE RIGHT HAS EXHAUSTED THE CYLINDER WITH GUERICKE'S AIR PUMP. FROM OTTO VON GUERICKE, "EXPERIMENTA NOVA," 1672

piston diameters in order to get the required power with the safety of low pressures. One engine, for instance, had a cylinder 21 in. (53 cm.) in diameter, a stroke of 7 ft. 10 in. (2.4 m.), and operated at 12 strokes per minute. The actual water raised showed that its effective horsepower was about  $5\frac{1}{2}$ . Thus the smallest Newcomen engines were about equal to the smaller windmills in capacity, but the larger engines were much greater in power than any unit of the earlier prime movers. The Newcomen engine, then, marks the effective beginning of the utilization of a new source of power. With changes introduced by John Smeaton (1724-92), the Newcomen engine held its place for about 75 years, being used almost entirely for raising water.

Though Newcomen's invention satisfied the need for a cheap, constant source of power that could be located anywhere, it had major faults. Besides wasting steam, it was not possible to get rotary motion directly from its walking beam and chain with available crank motions because only the downstroke was a power stroke. The engine could, however, pump water to a reservoir to power a waterwheel supplying rotary motion. The Newcomen engine used neither steam pressure nor the expansive power of steam. These faults were attacked by James Watt, whose work on the steam engine was basically a scientific and critical revision of the Newcomen engine.

#### 7. James Watt's Experiment: The Separate Condenser.

In 1763 Watt was given the job of repairing a model of the Newcomen engine used for instruction at the University of Glasgow. This engine, which had a 2-in. (5-cm.-) diameter piston and a 6-in. (15-cm.-) stroke, would run for a few strokes and then stop, yet the boiler seemed to be capable of supplying adequate steam. Watt analyzed the heat losses and the character of steam in imaginative quantitative experiments. He noted that loss of heat through cooling and reheating the walls of the cylinder was considerable and that this was probably the reason why the engine stopped. The idea occurred to him to keep the cylinder as hot as the steam that entered it to avoid useless condensation. There were two possibilities: a steam jacket on the cylinder to keep it warm, and a separate condenser and an air pump to avoid the alternate cooling and reheating of the cylinder. Thus the cylinder would be kept hot and the separate condensing chamber cool. His experimental piston-and-cylinder apparatus of 1765 consisted of a brass cylinder made from a syringe  $1\frac{1}{2}$  in. ( $4\frac{1}{2}$  cm.) in diameter

and 10 in. (25 cm.) long. The separate condensing chamber, made of tin and submerged in cold water, was designed to be cleared of air and water by a hand condensate pump. The separate condenser was connected to the cylinder by cocks or valves. Watt's experimental model raised an 18-lb. weight, and his calculation showed that the effective pressure was 13.6 psi (pounds per square inch) as compared to the 14.7 psi theoretically possible. This, of course, was considerably more efficient than the effective 7-8 psi of a Newcomen engine.

Watt demonstrated the soundness of his hypothesis by the efficiency obtained. In his device the work was done not by the atmosphere working against a steam-created vacuum but by steam working against a steam-created vacuum.

Watt's patent of 1769 claimed: first, jacketing the cylinder with insulation and/or steam to keep it hot; second, the use of a separate condenser kept as cool as possible; third, the use of an air pump to clear the condenser and cylinder; and fourth, the use of the expansive force of steam (although this was not embodied in his early engines). Watt demonstrated that the steam engine was a heat engine by striving for a maximum temperature differential between cylinder and condenser. In one sense, he was simply modifying the Newcomen engine, yet he added so many important inventions and innovations—and created the engine so nearly as it is today—that, by comparison with the usefulness of other engines, his engine was the strategic invention.

The design for Watt's early engine had certain disadvantages, however. It retained the chain acting on an arc at the end of the walking beam, and the engine was therefore still only good for pumping. The engine was single-acting (steam acting only on one stroke), and steam was still admitted during the whole stroke without any cutoff. Nonetheless, the design was based upon a sound, scientific perception of the properties of steam, and it marked an advanced concept that was to be carried much further.

**8. Development of the Steam Engine.**—The transition from Watt's concept of 1769 to engines in practical operation involved a number of technical and business problems, as well as long delays. First, Watt's ideal design outran the existing facilities for building engines. Though financial support was received from John Roebuck, a Scottish chemical and iron manufacturer, the high cost of developing the steam engine, along with his other engagements, forced Roebuck into bankruptcy. In a sense this was

CULVER PICTURES, INC.

THE ATMOSPHERIC ENGINE OF THOMAS NEWCOMEN

JAMES WATT'S STEAM ENGINE

fortunate for Watt, because in the liquidation of Roebuck's affairs Matthew Boulton, the great Birmingham manufacturer and entrepreneur, became interested and in 1773 took over Roebuck's share in Watt's patent. Boulton's contributions considerably hastened the production of Watt's engine. He provided a large engineering shop in which parts of Watt's engine were built in 1774, and he supplied the necessary resources, business experience, and technical knowledge to manage the firm successfully.

The demand for the early Boulton and Watt pumping engines was small, except in the Cornish tin mines, where coal was dear and the fuel economy critical (the Cornish owners contracted to pay for the Watt engines out of fuel savings). In other mines, where coal was plentiful, the Newcomen engine was reasonably satisfactory. When it became apparent that their huge enterprise required greater output than the demand called for, Boulton and Watt saw the need for developing an engine of more general industrial use.

The resulting double-acting engine and its power-transmission linkage were described in Watt's patents of 1781-82. In this engine steam was cut off before the cylinder was entirely filled, and the engine operated by the subsequent expansion of steam. These elements, which were essential to the general utility of the engine, marked the climax of Watt's work. They also marked a turning point in assuring the prosperity of the firm.

After 1784 Watt rated his engines in horsepower, having defined this as 33,000 ft.-lb. per minute. The first double-acting engine was capable of only 10 hp., but later engines developed 20 hp., and a few were rated at 40, 50, and even 80 hp.

The real advantage in Watt's work, however, was the increase in efficiency, which reduced the cost of operation and gave the engine a wider market. For a 40 hp. engine, an atmospheric engine re-

quired about 16 lb. of coal per horsepower hour, while Watt's double-acting engine required only about 8½ lb. of coal per horsepower hour. The double-acting engine with cutoff and an expansion of 1½ times required only slightly more than 6½ lb. of coal per horsepower hour. The Cornish tin mines recorded an actual reduction in coal consumption after the introduction of these engines to about one-third of what it had been with Newcomen engines.

The full exploitation of the steam engine developed in two directions: first, in higher pressures; and second, in the investigation of the thermodynamics of steam and its properties. With higher pressure more economical results could be obtained, and the steam engine could be applied to locomotion because of the consequent reduction of engine weight per horsepower unit and the possibility of dispensing with the condenser. Denis Papin had been on the verge of this development, and Jacob Leupold published a sketch of a high-pressure engine in the 1720s. Why then did it not appear earlier? The limiting factor was not the concept or a matter of design, since all the valves and the piston motions were much the same as those of the low-pressure engine. The cause of delay in going to higher pressures was that neither boilers nor cylinders were then available with the required strength and accuracy. Watt's fear of higher pressures discouraged other English engineers for a generation or more. In 1784 William Murdock, one of Watt's workmen, undertook a high-pressure locomotive action, but Watt discouraged it. It only became possible to go to higher pressures through improvements made from 1775 to 1800 in the manufacture of iron and in the working of metal. The first really significant high-pressure results were obtained by Oliver Evans of the United States and Richard Trevithick of Britain between 1800 and 1801.

#### B. TEXTILES

The mechanization of a basic consumer goods industry was a necessary preliminary to the British Industrial Revolution. The mechanized cotton factory, which became the most characteristic feature of the Industrial Revolution, is an excellent example of a continuing historical process of major significance.

**1. Beginnings of Mechanization.**—In earliest times fibres could be spun (twisted and drawn out) into yarn or thread without the use of tools. The bundle of fibres, after carding (combing) with thistle or teasel heads, was spun between one hand and leg, while the other hand drew out the yarn. The loom had warp, or lengthwise, threads. The weaver passed the weft, or crosswise, thread by means of a shuttle through the shed, or opening, made by raising simple heddle frames to which alternate warps were fastened. These simple movements of the carder, spinner, and weaver, however, proved subtle and complicated to the many inventors who tried to imitate them mechanically.

BY COURTESY OF THE METROPOLITAN MUSEUM OF ART, FLETCHER FJND, 1931

WEAVING OF WOOL ON A VERTICAL LOOM—DETAIL OF A PAINTING ON AN ATHENIAN SCENT BOTTLE, ABOUT 560 B.C.

Thousands of years before Christ, spinners began to use the free spindle for twisting the fibres. An early model was a wooden stick about half an inch in diameter and less than a foot in length. Near the bottom end of the spindle was a stone or clay disk, called the whorl, which gave momentum to the rotating spindle in the manner of a flywheel. While drawing out the fibres with one hand, the spinner would use the other hand to turn the spindle, which twisted the drawn fibres into yarn. As late as the 19th century, hand spinning with the spindle over a bowl of water to give the proper humidity was common in India, and cotton for the finest muslins was spun in this way.

Records and remains that would allow precise dating of innovations in textile production before the Middle Ages are scarce. In the 4th or 5th century A.D., unknown inventors in Europe introduced suspended heddles, which were rectangular frames hung above the horizontal loom frame. By means of cords attached to the heddle and to the warp yarn the shed was opened for the passage of the shuttle. With more than two heddles it was possible to weave fancy fabrics. Before the late Middle Ages, the suspended reed frame had been introduced for beating-in the weft of the horizontal loom to a tight fit. (See also SPINNING and WEAVING.)

**2. Mechanization of Spinning.**—The winding, or quilling, wheel probably came to the West from the Orient during the Roman domination of the Near East. In one of the earliest uses of continuous rotary motion, this wheel wound yarn from the spindle onto the quill, or bobbin, that was incorporated in the shuttle. The quilling wheel may have stimulated the invention of a wheel to drive the spindle, thereby creating a spindle-wheel. The spinning-wheel, which appeared in the 13th century, was essentially

the hand spindle with its whorl modified to make a pulley, and driven by a rope belt from a large wheel. The rigid spindle mounting, the momentum of the large wheel, and the speed ratio between the large wheel and the spindle pulley allowed greater output. Apparently the quality of this yarn was limited, for a drapers' guild of Speyer, Ger., in 1298 permitted wheel-spun yarn to be used in the weft but not in the warp, where a yarn of greater tensile strength was necessary. A major disadvantage of the spinning-wheel was the reversal of wheel motion between spinning and winding. After the twisting cycle, the wheel had to be rotated in the opposite direction for the yarn to be wound on the spindle.

The incorporation of a U-shaped flyer upon the spindle, a step taken in Europe during the mid-15th century, made it possible to spin and wind fibres simul-

taneously. The great wheel of the spindle-wheel, essentially a flywheel, carried two rope drives: one to turn the spindle and one to turn the flyer. Different speeds followed from the different sizes of the spindle and flyer pulley wheels. The U-shaped flyer turning around the bobbin twisted the yarn while the smaller pulley wheel turned the bobbin faster, causing it to draw out and wind the spun yarn. Even with the flyer, bobbin, and wheel drive, the spinner had to draw out the strand of fibres from the distaff and move the yarn from one flyer hook to another to wind the spool evenly. Later building motion caused the spool gradually to rise or fall on the spindle shaft in order to wind evenly.

The output of yarn greatly increased with the use of the spinning wheel, but it rose even further when by 1524 a crank, connecting rod, and foot treadle had been added.

**3. Developments in the British Textile Industry.**—The efforts of inventors and industrialists to replace human and animal muscles with mechanisms intensified in the middle decades of the 18th century in Britain. Because there existed a considerable disparity between the amount of capital available for investment in the textile industry and the available labour supply, the need for labour-saving mechanisms was great, and ingenious men found a more hospitable environment for their clever mechanical devices than formerly. The knitting machine invented in 1589 by William Lee, a curate of Calverton in Nottinghamshire, previewed in its effects the impact of the famous 18th-century inventions of John Kay, James Hargreaves, Richard Arkwright, Samuel Crompton, and Edmund Cartwright. John Kay's machine, patented in 1733, contained a shuttle that rode on the lower horizontal member of his loom's rectangular reed frame. Kay propelled his flying shuttle by use of a driver, or picker, at each end of the raceway. By jerking an attached cord in the direction in which the shuttle was to go, the shuttle impelled by the picker was sent flying across to the other picker. With the flying shuttle, the weaver greatly increased his output.

Mechanization of the loom was accompanied by mechanization elsewhere in the textile industry. Lewis Paul patented in 1738 a spinning mechanism that drew out fibres of wool (and later cotton) by a sequence of rollers. In his system of roller drafting, each successive pair of rollers revolved faster than the preceding pair, thus drawing out the loose sliver of carded wool in preparation for spinning. He also attempted to speed up another step in textile production with his carding machines of 1738 and 1748. Another machine patented in 1758 included a flyer and bobbin to spin the yarn.

Richard Arkwright improved upon Paul's roller-spinning system and brought it into widespread use. He supplied his wooden water frame (so named because shortly after its invention it was water powered) with four bobbins of roving (sliver drawn out from wool and slightly twisted). The four strands of roving, nearly 1 in. in diameter, fed into a series of pairs of rollers and were drawn out. Four flyers twisted the yarn, and the spinning attendant wound the yarn evenly on the bobbin, using the notches on the flyer, as was done on the 15th-century spinning wheel. The coarse, strong, well-twisted yarn of the water frame, or throstle, proved most suitable for the warp of the loom, and weavers were to use the yarn of other inventions—the spinning jenny and the spinning mule—for the weft well into the 19th century.

The spinning jenny, invented by James Hargreaves about 1764, resembled the spinning wheel even more closely and has been called a multiple spinning wheel. By the time Hargreaves had perfected and patented his machine in 1770, the flying shuttle had come into general use, and the rate of production from the loom dictated further mechanization of spinning.

The spinning jenny imitated the hand movements of drawing out, but it drew out eight strands simultaneously. It was a multiple spindle wheel with a bar clamp holding eight strands in a parallel and horizontal row. A single wheel with a crank drove the spindles, and a belt drive transmitted power from the crank to a beam, or large-diameter shaft, which in turn drove the separate yarn spindles by individual rope drives. The operator moved the carriage back and forth on the two longer top members of the frame with his left hand as he turned the crank with his right—

direction for spinning and the other for winding, as with the spindle wheel. Lower centre, across the short span of the frame, was a row of bobbins (eight in the original jenny). At the beginning of the spinning cycle, roving extended from the roving bobbins up to the moving carriage, under the bar clamp, and on to the yarn bobbins. The operator clamped the roving with the carriage bar when he had the desired length of roving between yarn bobbins and carriage. Then he pulled back on the carriage, drawing out the span of roving and simultaneously turning the spindles to unwind enough yarn to impart a twist to, and make yarn of, the roving. When drawing out was complete, a final spin gave the yarn a temporary excess of twist that was subsequently imparted to the contiguous roving. Then the direction of the wheel reversed to wind the new yarn. The operator released the carriage bar clamp and moved the carriage forward to take a new bite of roving when roving again spanned the distance from roving to yarn bobbins.

Samuel Crompton, who became annoyed with the malfunctionings of the jenny, devoted his modest income and considerable ingenuity between 1774 and 1779 to improving the design; ultimately he combined the rollers of Arkwright and Paul with the basic spinning-winding principle of the jenny. He aptly named his cross of the water frame and the jenny a mule. Mule spinning proved suitable for the weft, while the water frame produced a coarse, strong cotton yarn suitable for the warp.

In the 1770s Richard Arkwright combined many of these mechanical inventions into a factory system of production. The early mills or factories usually concentrated upon cotton production, partially because cotton could withstand the strains of the mechanized process better than wool.

**4. Mechanization of the Loom.**—Kay's flying shuttle had mechanized the shuttle throw, and, since the 13th century, foot treadles had lifted the warp to make the shed. Besides Kay's invention the other major 18th-century improvements were the

but Joseph Marie Jacquard, drawing upon their prior experience, built a practical automatic drawing mechanism.

Born in Lyons, a centre of the silk industry, Jacquard invented a device which was a forerunner of 20th-century punch-card controls, but the Jacquard control was mechanical rather than electronic. A punched card for each throw of the shuttle determined the selection of warp threads lifted to form the shed. A master designer punched the cards, and even pictorial representations could be woven by a card sequence. The cards replaced the draw-boy, and a set of cards once punched could be repeated as often as the market demanded. By 1833 Lyons alone had 60,000 persons employed in the manufacture of figured goods with Jacquard looms.

Early Jacquard looms were not power looms. Whether a drawloom with Jacquard attachment or plain, the loom proved difficult for adaptation to steam or water power. Edmund Cartwright (1743–1823) became aware of the need for power weaving to keep pace with the potential of high-output spinning machines. Despite his lack of mechanical experience, Cartwright invented a power loom, which he patented in 1785. His loom was a crude affair that never achieved commercial success, although it incorporated the basic features of an automatic power-driven sequence of operations. The model that emerged as the most practical was that of Richard Roberts (1789–1864), a machine maker of Manchester. His loom of the 1820s involved an automatic sequence for driving the batten, raising the warp to create the shed, throwing the shuttle, and winding the woven cloth.

**5. The Cotton Gin.**—The mechanization of spinning not only stimulated development of improved looms but it also created an enormous demand for cotton fibre. The soil and climate of the southern United States were particularly well suited for growing cotton of the short-staple, green-seed variety. Existing methods for removing seeds from the raw cotton required it to be done slowly by slave hand labour.

EIGHTEENTH-CENTURY LOOMS AS SHOWN IN DIDEROT'S "ENCYCLOPÉDIE"

mechanization of the plain loom and drawloom. A plain loom could weave patterns if the number of heddles to raise the warp selectively was increased, but it then became rather cumbersome. The answer was the drawloom, which had long been used in the East for weaving silk. Essentially the drawloom substituted a figure harness for the large number of heddles that would be necessary for figured designs. The figure harness was simpler to operate, and with the aid of an attendant, or drawboy, cords were worked to raise the warp threads, which were gathered into groups as required by the pattern.

In the 18th century French inventors strove to replace the drawloom with a mechanism. Because France was famous for figured silk cloth, the pressure for a labour-saving draw mechanism was greater there than in Britain or other nations, where relatively plain woollens or cottons predominated. Basile Bouchon, his associate Falcon, and Jacques de Vaucanson (1709–82) designed imperfect devices,

Eli Whitney (*q.v.*; 1765–1825) designed and built a cotton-seed cleaning machine, the cotton gin, during the winter of 1792–93. His gin was a simple machine which, depending upon its size, could be powered by man, animal, or water. It received raw cotton from a hopper, caught the cotton on the wire teeth of a revolving cylinder, and drew the fibre but not the seeds between narrow iron slots of a breastwork. Revolving brushes cleared the clean fibre from the cylinder teeth.

Though he was granted a patent in 1794, Whitney did not profit greatly from his invention, since infringements of the patent were common. The gin, however, brought widespread cultivation of cotton in the South, and the Southern planters exported to Liverpool and other cotton ports, as well as to the young textile industry of New England. What had once been a relatively minor agricultural crop, painstakingly prepared by hand, rapidly became a mainstay of the economy.

## C. TRANSPORTATION

Development of an international cotton industry and the creation of a factory system of production would have been frustrated if it had not been for the development of a transportation system allowing the economical flow of trade from raw material, through manufacturer, to market. Especially important in the early years of industrialization were the inland canals and ocean navigation. Adam Smith (1723-90), writing in *The Wealth of Nations* on the eve of the canal era, foresaw the impact that an improved system of inland communication would have upon the economy. He observed that historically industry had generally flourished in those areas where water transportation was possible.

During the 18th century Britain drew upon the Continent for civil engineering knowledge to build her own transportation network. Skilled and experienced Dutch engineers were utilized to execute drainage works, build harbours, and make rivers navigable. But during the 19th century, when British engineering achieved new heights, the flow of technical knowledge reversed. Samuel Smiles, writing in 1861, observed "after the lapse of a century, we find the state of things has become entirely reversed. Instead of borrowing engineers from abroad, we now send them to all parts of the world." This dramatic reversal had taken place during the Industrial Revolution.

**1. French Engineering Accomplishments.**—The 17th and 18th centuries had been distinguished by triumphs of French engineering. Sébastien Le Prestre de Vauban (1633-1707), Bernard Forest de Belidor (c. 1693-1761), Jean Rodolphe Perronet (1708-94), and Jacques Gabriel (1667-1742) built bridges, harbour works, and roads during an era when the state stimulated and regulated the economy to further national interests.

The emphasis upon engineering during the reign of Louis XIV demonstrated the dependence of a would-be centralized regime upon the civil engineer. The network of roads, bridges, canals, and navigable river channels, constructed by the government corps of engineers, not only supported commerce but also tied together the provinces physically and politically. The interdependence of transportation-communication facilities and the effectiveness of a centralized political authority has been manifest throughout history. The intendants of Louis XIV were given a special responsibility to enhance this power through promotion of communication, transportation, industry, and commerce.

When Jean Baptiste Colbert (1619-83) became Louis XIV's chief minister, he not only regulated prices and quality but encouraged French industry by subsidy and tariff protection. He also initiated a road-building program and provided for the construction of great harbours at Brest and Rochefort. During his ministry French civil engineers organized the Corps du Génie, an association that encouraged its members to exchange technical information and discuss problems of common interest. As a result of the stimulus given by Colbert, French engineering continued to flourish after the reign of Louis XIV despite the increasing political debility of the monarchical government. In 1716 the famous Corps des Ponts et Chaussées was formed by the engineers who planned the roads, bridges, and canals of France, and in 1747 the École Nationale des Ponts et Chaussées became the modern world's first school of engineering.

Colbert provided for the construction of one of Europe's great engineering works, the Canal du Midi, or Languedoc Canal, which joined the Mediterranean and the Atlantic. The canal, begun in 1666, was opened in 1681 and perfected by 1692, giving passage across southernmost France and making unnecessary the voyage around Spain via Gibraltar for ships of suitable draft. Pierre-Paul Riquet (1604-80), an organizing genius with the conceptual power of a great engineer and the valuable support of Colbert, was appointed contractor for the canal, and by 1669 he commanded a work force of 8,000 men.

The Canal du Midi has been considered by some 20th-century engineers the greatest civil engineering feat in Europe from Roman times to the 19th century. Shipping utilized the navigable portion of the Garonne River from its mouth, near Bordeaux, to Toulouse. The canal rose 206 ft. (63 m.) by means of 26 locks in the 32 mi. (52 km.) from Toulouse to the summit level.

of the canal extended for 3 mi. (5 km.), and then the canal dropped 620 ft. (190 m.) by means of 74 locks in the 115 mi. (185 km.) to the Mediterranean near Sète.

A major problem for a canal with a high rise was supplying water at the summit level for feeding the locks in the two descents. Riquet suggested a supply from mountain rivers and streams near the summit level and the use of a storage reservoir for dry seasons. His concept proved conspicuously successful. Other solutions devised by Riquet and his staff of engineers included construction of the Malpas Tunnel, through which the canal passed for 180 yd. (165 m.); major aqueducts, which carried the canal over intervening rivers; and culverts, which carried numerous streams under the canal.

This great engineering achievement, along with other engineering accomplishments in Europe prior to the Industrial Revolution in Britain, made available to the British a vast accumulation of technical knowledge through contemporary descriptive literature. The *Philosophical Transactions* of London's Royal Society, for example, carried detailed accounts of the Canal du Midi, and there were authoritative works on engineering, such as C. A. de Coulomb's *Essai . . . à quelques problèmes de statique . . .* (1776), in which he introduced the use of calculus in engineering theory. Thus the written word, firsthand observation, and oral reports served to diffuse the French civil engineering experience to a nation needing communication and transportation facilities, especially such waterways as canals.

**2. British Civil Engineering.**—Generally, the economy of a canal as compared to other available means of inland transportation could be demonstrated by the load a horse could draw or carry: a pack horse could carry  $\frac{1}{2}$  ton; a horse drawing a wagon, about 1

LATHE DESIGNED IN 1843 BY SIR JOSEPH WHITWORTH

ton; a horse pulling a wagon on rails, 8 tons; and a horse drawing a canal barge, 50 tons. If the transportation demand were heavy, the capital expenditure would be offset, then, by the mechanical efficiency of the canal system.

The first British canal of major economic significance was begun by James Brindley (1716-72), with the financial support of the Duke of Bridgewater. The duke needed a canal for transporting coal from his mines at Worsley to the textile manufacturing centre at Manchester, a distance of 10 mi. (16 km.). Since the price of transporting the coal was halved after the canal was built, the duke believed that further benefits would accrue if the canal were extended from Manchester to Liverpool, an additional 30 mi. (48 km.).

After Parliament enacted a bill authorizing his engineering project, the duke employed Brindley, an unschooled millwright, who had won a reputation in the district, to carry out the project. Brindley encountered major engineering problems and responded with solutions characterized by bold conception, organizational genius, patience, and perseverance. His equal facilities in mechanical and civil engineering were revealed by the transportation-drainage system he provided in the Worsley mines and which he integrated with the canal system. A subterranean channel hewn out of rock extended from the barge basin at the head of the canal into the workings of the mines; this channel acted as a mine drain, as a feeder for the main canal at the summit level, and as a small barge-carrying canal. Within the mines Brindley used railways to move coal from the subterranean vein to the channel, and at Manchester he erected a waterwheel-driven hoist to lift the coal from the barges up to the populated area. Thus he had planned a mechanized transportation system by which the coal moved from the face of the coal in the duke's mines to the consumer at Manchester or Liverpool. The canal system from Worsley to Manchester cost £220,000, but the annual income rose from £12,500 in 1776 to £80,000 in 1792.

Several other civil engineers of Brindley's time deserve mention. John Smeaton (1724-92), of whom James Watt said, "his example and precepts have made us all engineers," numbered among his triumphs the historic lighthouse on Eddystone reef off the Cornwall coast near Plymouth. This structure, built under the most trying circumstances, was designed of interlocking stone blocks dovetailed to the reef to withstand the fury of the sea. Smeaton also improved the efficiency of the Newcomen engine, and he planned the Forth and Clyde Canal, which in 1790 joined Scotland's east and west coasts.

Thomas Telford (1757-1834), whose great engineering works included a magnificent suspension bridge across the Menai Straits, was one of the outstanding engineers of the Industrial Revolution. Like John Metcalf and J. L. McAdam, Telford was self-taught, but all three men gained fame as prominent road builders.

The transportation facilities built by these engineers considerably stimulated the revolutionary pace of industrial growth in Britain after 1770. For example, by cutting a waterway from Liverpool to Manchester and through the counties of Chester, Stafford, and Warwick, Bridgwater and Brindley opened the way for the industrialization of northwestern England—now England's most densely populated area—and for the creation in Manchester of the world's greatest cotton-manufacturing district.

## VIII. THE WATER TURBINE

The development of the steam engine proved the basis for a general use of power in industry. While it overcame serious limitations of waterwheels and windmills, and it produced large amounts of power in any location where fuel was available, there were certain limitations, since coal supplies were often inadequate at established industrial centres where power was being applied. However, there were many sources of water power available in areas without coal. Because many of these sources were not suited to either the undershot or the overshot wheel, especially of the size possible of construction at the beginning of the 19th century, there was a demand for a new type of hydraulic motor. There were many attempts to utilize these sources of power more completely, but, until the turbine appeared in the 1830s, they met with little practical success.

**1. Steps Leading to the Invention of the Turbine.**—The water turbine operates on a principle quite different from that of the waterwheel. In the overshot wheel, power is obtained from falling water, while in the undershot wheel, power is obtained from the impact of rapidly flowing water. But in these waterwheels there is no motion of the water relative to the buckets of the wheel doing work. In the turbine, however, power is derived from impulses set up between the fast-flowing water and the curved passages in which it is contained. This means that the water must be confined either in tubes or in channels set up between vanes in a close-fitting case, and there must always be movement of water relative to the vanes.

The first evidence of the transition from the horizontal waterwheel to the turbine appeared in one of Leonardo da Vinci's sketches. His device showed curved vanes set at an angle to the axis of rotation, but it had no casing. Bernard Forest de Belidor in 1737 described a device similar to Leonardo's in which the wheel was raised above the tailrace level. It therefore operated as a water turbine with partial emission of the water, since it had no casing. Wheels of this sort came into common use by the second half of the 18th century in southern France and Italy. Jacques Besson in 1579 provided one of the earliest drawings of a water turbine. This was the pit or tub wheel, a cone-shaped wheel with vanes that was fitted into a masonry pit. Although water acted on these vanes by both impact and weight, the gap between the wheel and the masonry pit resulted in a large escape of water. By the beginning of the 18th century the clearance had been improved and there was more economy in the turbine's operation. A wheel built at Toulouse early in the 18th century was more nearly a turbine. The river water was guided into a masonry sluiceway and aimed at the vanes of a Belidor-type horizontal wheel. Though the vanes had been transformed in shape and were joined by a casing, it was not a full turbine because there was a substantial gap between the wheel and the casing and therefore considerable escape of water. However, the wheel was completely submerged.

By the second half of the 18th century much practical empirical success had been achieved. Further development followed: (1) a critical revision of the various horizontal water turbines commonly used in southern Europe from the 15th to the 16th century, and (2) the development of the science of hydraulics by experimental and mathematical analysis. A simple reaction wheel produced in 1750 by John Andreas von Segner was studied by Leonhard Euler, who analyzed its problems in scientific terms and was thereby led to the development of a crude turbine in which a fixed upper portion formed a cylindrical reservoir. Small tubes inclined at a calculated angle delivered water to an annular trough of the lower portion, which turned clockwise on an axis. From the bottom of the trough 20 tubes diverged as they descended to horizontal ends, ejecting the water to the air. This turbine was purely experimental, and though it may have had some commercial use, its real significance was that it represented the initial invention of the reaction turbine, based upon scientific analysis. Claude Burdin tried to improve the efficiency of these wheels and to develop the Euler reaction turbine further. In 1822 he produced an original design in which the wheel was completely submerged and the water was guided to the rotating vanes by a stationary inner case having guide-vane compartments. There were important defects, however, in Burdin's design; the inner surfaces of the moving vanes were too flat to get the full effects from the impulse and the reaction that were necessary for significant operation, yielding insufficient power for efficient use.

**2. Invention and Development.**—Benoît Fourneyron, a student of Burdin, became interested in the problems of the reaction wheel and began active work on the turbine in 1823. By 1827 he had developed a small turbine of about 6 hp., for which he won a prize from the Society for the Encouragement of National Industry. Fourneyron's invention received further support from F. Caron, a forgemaster, who ordered a 10-hp. turbine for his blowers and later ordered a 50-hp. turbine for his forge hammers. In 1832 Fourneyron produced and patented a 50-hp. wheel that also won a prize. The wheel consisted of a stationary inner part with gates that could control the water. The moving portion was the outer wheel in which there were two annular iron plates supporting 30 curved vanes. Actually this combined both impulse and reaction, but it is significant that it could operate with a head of only 4.59 ft. (1.4 m.). However, Fourneyron's next turbine, which produced 40 hp., operated with a head of 354 ft. (108 m.). No previous hydraulic motor could utilize such varied sources of water power and give so much power.

The development of the turbine from 1832 to 1855 was characterized by much variety in design. Although both reaction and impulse turbines were tried, the impulse turbine was better adapted to streams of varying flow and to high heads of water of small volume. The crucial invention for the impulse type of turbine was

the work of Pierre Simon Girard, who in 1855 invented a device for "ventilating" the vanes by providing air spaces at their inner bend so that the water would not completely fill the interval between the vanes.

Variations in flow methods also led to a number of different types. Fourneyron's reaction turbine operated with radial flow outward, but in the U.S. James Thomson about 1851 and James B. Francis in 1855 produced reaction turbines with radial flow inward, and this became the predominant American type. The French inventor Jonval in 1841 produced reaction turbines with axial flow, some up and some down. There were also many combinations of radial and axial flow in reaction turbines. Girard's turbine with axial flow either upward or downward became the commonest impulse type.

The wheel of the simple impulse turbine originally had fixed, flat vanes around its circumference. An improved form, developed

that on a large ship, permitted high speeds with a low head of water. By 1940 Nagler runners had come into extensive use.

Nagler's propeller turbine operates at maximum efficiency with a constant head and with a constant volume of water. Furthermore, any variation in the power load required causes a decrease in efficiency. A propeller patented by Victor Kaplan in 1920 enabled the turbine to give increased efficiency at heads greater or less than normal and therefore an increase in output under unfavourable conditions. In order to match more accurately the correct angle for a given flow of water, Kaplan provided fixed gates but adjustable runner blades.

## IX. DEVELOPMENT OF THE RECIPROCATING STEAM ENGINE

**1. Improvements by Watt's Successors.**—Many improvements were made in the design and construction of the reciprocating steam engine in the century following James Watt's work, but no alteration in principle was introduced until the appearance of the steam turbine in the 1880s.

Since Watt never used boiler pressures greater than 10 psi, he found no advantage in cutoff of the steam earlier than one-fifth of the stroke or in the need for more than one cylinder. However, with the work of Jonathan Hornblower, one of Watt's contemporaries, there was the first appearance of the compound engine in which the steam passed successively through two cylinders. In 1781 Hornblower actually tried out an engine of this sort, but the courts decided that it was an infringement of Watt's patents. Arthur Woolf in 1804 built the first high-pressure compound engine, which expanded the steam to several times its original volume and was therefore much more efficient than Watt's engine. Woolf did not run into patent difficulties because Watt's patents had expired in 1800.

Actually the very extensive provisions of Watt's patents held back the development of the reciprocating steam engine in England. Also, the commercial success of the firm of Boulton & Watt led any innovators to have serious doubts about trying any other type of engine. However, William Murdock in 1785 built a high-pressure engine with a vertical oscillating cylinder. This engine, which was single acting and had a piston that acted directly on a crank, also used the D-slide valve for the first time.

From 1800 to 1860 the general design of pumping engines remained nearly constant, even though some of the details were altered and simplified. However, the engine for driving machinery underwent considerable development. The walking beam typical of the Watt and the Newcomen engine was a cumbersome device. With the invention of the planing machine by Richard Roberts in 1830, it was possible to replace this awkward piece of machinery by a crosshead and a connecting rod acting directly on a crankshaft and carrying a flywheel.

Watt's engines were expensive to run, for they burned about 94 lb. of coal per horsepower hour, and, with low pressures of 5-10 psi, they required both a condenser and an air pump. The solution was sought in higher pressures. In the United States this was tried by Jacob Perkins, Oliver Evans, and John Stevens, and in England by Richard Trevithick. All of these men went immediately to pressures of 50-70 psi, but the work of Oliver Evans was by far the most influential. He established the high-pressure engine in the United States, and by 1860 pressures of 60-80 psi were common, whereas in England engines at this date were all working with less than 60 psi.

**2. Greater Efficiency.**—The increasing size of reciprocating steam engines in the 19th century meant that central in their development was a struggle for higher efficiency. This took two forms: (1) the study of devices for admission and control of the steam, which eventually permitted a more effective steam cycle; and (2) the development of a theoretical analysis of exactly what happens inside the steam cylinder, which finally permitted a scientific design of the action of the engine.

**Devices for Controlling the Steam.**—Murdock's D-slide valve was replaced by the short D-valve on small engines and by the long D-valve on larger units, although both had certain disadvantages. The D-valve could not cut off the steam earlier than one-half the

BROWN BROTHERS

THE 50-HP. FOURNEYRON TURBINE, 1832

about 1854, had spoon-shaped buckets fitted to the rim of the wheel to which a jet of water was applied tangentially. A wheel designed in the 1880s by Lester Allen Pelton resulted in much higher speeds and considerably less splashing. Pelton's wheel used a centre ridge in each bucket to split the water jet so that it would glide smoothly over the two halves. This type of wheel has found application in many modern installations.

Another important step was taken in 1910 by Forrest Nagler, who produced a much lighter and simpler type of runner for reaction turbines. His work went back to that of Jonval, who had developed a reaction turbine in which the flow was purely axial. The runner of Jonval's turbine consisted of a narrow row of blades on a large disk. Nagler replaced Jonval's design with one in which there were a few stationary flat blades at the end of a cylindrical casing, the openings between the blades being governed by movable gates, or wickets. This runner, which in effect was a propeller similar to

stroke without throttling or "drawing" the steam as it entered the cylinder. The long D-valve provided a shorter passage for the steam, but its longer travel and larger rubbing surface produced great friction, especially with higher pressures. Later the doubleported valve reduced both friction and throttling. The Meyer expansion valve, which was introduced to give a sharp and variable cutoff without changing the exhaust, consisted of two slide valves, one mounted on top of the other and each driven by a separate eccentric. The lower of these was an ordinary slide valve with its ports passing right through it. The upper valve consisted essentially of two blocks on one rod that had right- and left-hand threads. These blocks covered and uncovered the openings in the lower valve, but by rotating the rod the blocks could be brought closer together or farther apart, thereby regulating the cutoff and the expansion of the steam.

The cylindrical valve was in use before 1840. It consisted of two pistons on a rod operated by an eccentric. The valve chest was usually mounted alongside the cylinder, and the pistons were made tight by metallic rings. The cylindrical valve had many advantages: it was easy to achieve steam-tight contact with the valve chamber; the rubbing surfaces were small; and, since the steam could be admitted between the two pistons, it produced a balance of the pistons and little pressure on the bearing surfaces. The packing of the gland of the piston rod had the advantage that it was subjected only to exhaust pressures and not to the full boiler pressure. The small amount of friction meant not only that there was little wear but that little power was required to operate the valve itself. The cylindrical valve was expensive to make, yet it was effective, especially with increases in steam pressure. It is still commonly used on the high-pressure side of compound engines, but it is not easy to vary the cutoff and therefore is not adapted to governor control.

As the steam engine came to be used more and more for driving machinery, it was essential to secure uniform speed of operation. This led to the use of the flywheel, which served as a reservoir, alternately storing and restoring excess energy resulting from the variations of turning action of the connecting rod in relation to the crank. It also to some extent prevented sudden changes of speed from variations in load.

A governor was also needed to maintain constant speed. This had been introduced by Watt in order to prevent variations in speed greater than a certain amount when the load was altered. Watt's method had been to use the governor to vary the amount of steam fed to the cylinder by opening or closing the throttle valve. Governors of this sort persisted well into the 20th century. With the Wilson Hartnell governor (1885), which controlled the speed to within a variation of 1.25%, it was simpler to alter the cutoff and so regulate the steam entering the cylinder at the latest possible moment rather than to control a throttle valve.

The famous Corliss valve gear, patented in 1849, had four valves, one admission and one exhaust at each end of the cylinder. The four valves were cylindrical and turned through a small angle, and all were operated by a single eccentric. Drop valves of the balanced type were also introduced to overcome the limitations of sliding and rotating valves. The most prevalent type of valve for larger stationary engines was the Meyer expansion valve, controlled by a Hartnell governor. Typical practice in the U.S. in 1876 for engines up to 250 hp. was, however, to use a D-slide valve, with a governor acting on the throttle.

In 1876 condensers were not in general use in the U.S., though they were quite common in England and on the Continent. Pressures of 80–100 psi were common in the U.S., but European pressures were seldom more than 75 psi. Thus the concern with improved efficiency had led to a number of different types of valves and valve gears, but few of the many devices introduced from 1800–60 actually persisted.

**Theoretical Analysis.**—Engineers in this period were obsessed with the economy to be obtained through the expansion of steam, but there was a limit to what could be secured from improved valve design! It took some time to recognize the losses incurred by contact of the steam with the cooler surfaces, even though Watt had noted that the reduction of these losses would improve the

efficiency of the engine. The U.S. engineers first recognized the importance of short stroke and high speed in order to produce a condition in which the steam was in contact with the smaller area of the cylinder wall for a shorter time, thereby reducing the initial condensation as well as the loss of heat through both piston and cylinder walls, both of which were then cooled by the exhaust steam of the previous stroke. These observations became clear as a result of theoretical studies and experimental research on the properties of steam, as well as the application of scientific analysis to the steam engine.

The theory of the steam engine in Watt's day was very limited. Boyle's law of gases was known, but it was not until 1801 that Charles's law was announced. Joseph Black at Glasgow, who was Watt's friend, had measured the latent heat of steam. Watt repeated this for himself and determined the temperature of steam at various pressures. From about 1800 onward, however, there were two lines of important development: the determination of the actual properties of steam; and an understanding of the relationship of heat and work.

In 1825 the French government sponsored a determination of the temperatures of water vapour under pressures as high as 350 psi, and in 1843 the United States government initiated a similar project. The investigations begun in 1847 on the properties of steam by Henri Regnault proved to be the most accurate and the most comprehensive up to that time. It became clear that first, the latent heat of steam varies; second, the total heat increases by 0.305 units for each degree of increase in the liquid boiling point; third, the specific heat of superheated steam is equal to 0.4805; fourth, steam does not obey Boyle's law, which is true only for perfect gases; and fifth, steam is not a gas but a vapour. The concept of saturated steam was also introduced. Regnault pointed out that superheated steam does not condense on cooling until its temperature has fallen to the boiling point of water at that pressure.

These results were of tremendous importance in providing engineers with data for the study and design of steam engines, and they remained standard for nearly 50 years. Between 1915 and 1924 H. L. Callendar collected, critically examined, and tested the whole body of knowledge about the properties of steam, and the result was the compilation of the first genuine set of tables on steam. These were replaced in 1936 by the tables of Joseph H. Keenan and Frederick G. Keyes, who provided new accuracy and data relating to higher temperatures and pressures.

Along with the growing knowledge of the properties of steam, there developed a fundamental knowledge of thermodynamics. While in charge of the boring of cannon in the arsenal in Bavaria, Benjamin Thompson, Count von Rumford, in 1798 noted the tremendous amount of heat that was produced. Careful measurement of the work done and the heat produced led finally to a value of the mechanical equivalent of heat of 783.2, an error of only 1%. Moreover, the caloric theory of Antoine Lavoisier and his predecessors was replaced by the dynamic, or kinetic, theory of heat.

Little attention was paid to Rumford's work at the time, though he is known today as the founder of thermodynamics. But during the next 50 years considerable advance was made. In 1824 Sadi Carnot showed that since heat only does work as it falls from a higher to a lower temperature, the efficiency of the ideal heat engine is independent of the working substances and depends only on the initial and final temperatures. Carnot's theory was gradually modified and adapted, and it remains one of the most important elements in the theory of the steam engine, as well as a cornerstone of thermodynamics.

The dynamic theory of heat was not fully accepted until more accurate and comprehensive experimental evidence was available. In fact it was not until the work of James Joule, between 1840 and 1850 that the kinetic theory of heat was definitely established.

All this theoretical work was expressed in abstract and mathematical form far beyond the capacity of most engineers, and before 1850 it had little, if any, direct influence on the design of the steam engine. Application of these theories came about as a result of the work begun by William J. M. Rankine in 1849, in which he showed that condensation must take place in expansion. His re-

suits were corroborated by Gustave Adolphe Hirn, who in utilizing a glass cylinder observed the actual formation of the mist. Rankine's work was incorporated (1859) in a classic of technology, *A Manual of the Steam Engine and Other Prime Movers*, which gave the first systematic account of steam power. Rankine showed that if the cylinders and pistons behaved as nonconductors of heat, the volume of steam consumed per stroke would be equal to the volume of the cylinder up to the point of cutoff. But these surfaces are not nonconductors. Since they are cooled by the exhaust steam of the previous stroke, they cause some condensation of the entering steam and therefore require an increase in the volume of the steam. The water thus condensed is reevaporated during expansion, resulting in a loss of heat energy. Rankine showed that this loss may be considerable and that it could seriously affect the design of the engine.

By 1860, then, a genuine theory of the steam engine clearly indicated that, if high efficiency were to be obtained, the essential elements would comprise: first, high boiler pressures; second, high initial temperature in the cylinder; third, a relatively short stroke to diminish admission condensation; fourth, expansive working; and fifth, low condenser temperatures. To incorporate these principles in the actual design of an engine required a combination of British and American practices and even higher pressures than those in use in the U.S. The greatest possible efficiency in the condenser and the air pump, a development that came later, was more closely connected with the development of the steam turbine.

**3. From 1870 to 1900.**—The development of the steam engine from 1870 to 1900 was characterized by high pressures, high speeds, and high efficiency. These goals could not be achieved by the development of theory and the accumulation of experimental data alone. They also required new materials, new workshop processes, and new demands for power. The demand for larger engines and more economy became greater as the mills and workshops increased in size.

In 1854 John Elder successfully launched a ship having a compound engine, and this led to land use of similar engines, particularly since they reduced coal consumption from 4 to 2½ lb. per horsepower hour. However, the demand for larger units on land

1871; the Willans central-valve engine of 1885; the Belliss and Morcom quick-revolution engine of 1890; and the uniflow engine, first designed in 1885 but finally successful in 1908.

Peter Brotherhood patented an engine in 1871 that had three cylinders arranged radially about a crank, with steam admitted through a rotary valve. It was intended to drive high-speed machines directly, without gears or belts. Brotherhood engines were built in sizes from 7 to 35 hp. and used pressures of 40 psi. The largest engine operated at 225 rpm, which was about twice the speed of ordinary reciprocating steam engines of the 1870s. These engines were used on the French warship "Richelieu" in 1875 to drive the first direct-driven dynamo, as well as the ship's centrifugal circulating pumps. In 1878 the first self-propelled torpedo to sink a warship in action had a Brotherhood-type engine. By 1895 about 7,500 of these engines had been built, and they continue to be made today.

The central-valve engine of P. W. Willans, originally designed in 1874, was perfected in 1885. Engines of this type were commonly compound or triple expansion, except for the smallest sizes, the cylinders being arranged vertically in tandem and the pistons mounted on a common connecting rod that was tubular and had ports. Steam was admitted at the upper end of the tube, and the cylindrical valves inside the piston rods were on a long rod that covered and uncovered the ports, the central valve being operated by an eccentric on a crankpin. The work cycle of this engine is of some interest, because the work was done by difference in pressure on two sides of each piston on the downstroke. On the upstroke the pressures were the same on both sides. This engine also had an air buffer by which compressed air compensated for the inertia of the parts on the upstroke, so that there was no reversal of load on the bearings on the connecting rod or on the crankshaft main bearings. The result was very quiet operation and little wear. For 20 years engines of this sort were used largely for driving dynamos, and a great number of them were built. They had very low steam consumption, but the power-to-weight ratio was rather low, and the mechanical efficiency was less than 90%, even for a double-acting engine.

The Belliss and Morcom quick-revolution engine of 1890 was lighter and less expensive than the Willans engine. It operated at higher speeds and therefore permitted smaller and less expensive generators to give the same output. It had a short stroke and high shaft speeds with low piston speeds, and it was one of the first engines to have forced lubrication, for a pump supplied oil to all the rubbing surfaces at a pressure of 10–20 psi. This engine, which operated at 625 rpm, was commonly vertical and totally enclosed to keep out the dust. The original engine ran 10–12 hr. a day for 29 years, often overloaded on its designed horsepower of 20. It is estimated that it made 4,000,000,000 revolutions and when disassembled showed very little wear. The basic features were also built in compound and triple-expansion engines, the

latter having three cranks 120° apart to give a uniform turning effect. The use of higher pressures in superheated steam would have been impossible without the features of this engine, especially its use of metallic packing and mineral oil for lubrication.

The uniflow engine developed in 1885 by T. J. Todd had exhaust ports in the centre of the cylinder. These were opened and closed by a very long piston, thereby avoiding the alternate heating and cooling of the cylinder ends by the exhaust steam. The steam entered only at each end and then discharged in the centre. Todd's engine attracted very little attention until 1908, when J. Stump

did not become significant until the late 1800s, by which time steamships were using triple-expansion engines. Large land installations were usually only compound engines, but with their application to electric power stations there was a tendency to follow marine practice until large, vertical, triple-expansion reciprocating steam engines became standard. Within a dozen years, the steam turbine drove them out of existence, and within 25 years the diesel engine produced serious competition for the turbine.

In the further development of the reciprocating steam engine there were at least four landmarks: the Brotherhood engine of

designed more suitable valve gears for it. The engine then came into rapid use, and by 1914 several hundred were being used to drive generators, fans, rolling mills, colliery winding gears, ships, and locomotives. This engine occupies less floor space than any other horizontal engine of equal power and can be as efficient as a triple-expansion engine, with the additional advantage that its efficiency varies little with the load.

With the uniflow engine and the triple-expansion high-speed vertical engine, the story of the reciprocating steam engine ends. Further progress was to be made with steam power but through the use of the steam turbine rather than with the reciprocating steam engine, although there are many conditions to which the reciprocating steam engine is still peculiarly adapted.

## X. EVOLUTION OF THE STEAM TURBINE AND THE STEAM BOILER

### A. THE STEAM TURBINE

**1. De Laval's Turbine.**—The basic principle of the steam turbine was not new. About the 1st century A.D. Hero of Alexandria described a device that was essentially a reaction turbine, and Giovanni Branca experimented with an impulse turbine about 1629. But the work of these men did not have any commercial importance, and it was not until the latter part of the 19th century that any significant contributions were made. Carl G. P. de Laval of Sweden, one of several pioneers in the development of the steam turbine, built a small 42,000-rpm reaction turbine in the early 1880s. But he is better known for his work in developing the single-stage impulse steam turbine.

The basic principle of De Laval's impulse turbine was to have one or more steam jets directed upon a number of radial blades fixed at an angle around a single disk. With this arrangement of blades and jets, if the steam enters the atmosphere abruptly from one or more small nozzles its velocity is very low. But if the nozzle is designed to produce expansion of the steam, there is an enormous increase in velocity. In fact, if the steam is expanded into a vacuum from a properly designed nozzle, the steam velocity can be of the order of 3,000–4,000 ft. per second. Despite the fact that the mass of the steam is relatively small, its high velocity permits considerable work to be done. The problem of nozzle design to ensure maximum expansion of the steam and therefore maximum increase in velocity was not actually solved by De Laval until 1888. Nonetheless he was able to design an effective impulse turbine without having nozzles of ideal design. His main problem was the centrifugal stresses set up at the high peripheral speeds demanded for an efficient turbine. The actual turbine disk had to be made of high-tensile steel, and it had to be in perfect balance. Since the centrifugal force increases as the square of the velocity, any inequalities that were negligible in the disk at slow speeds become enormous at high speeds. There was a further problem in adapting the impulse turbine to the actual drive of mechanisms. Because the speed of the turbine was too high for direct drive even of electric generators, De Laval had to use high-speed reduction gears. For satisfactory operation it was necessary to have wheels with wide but small teeth that were cut in helices in order that more continuous and uniform force could be exerted by the driver.

Though De Laval's first impulse turbine of 1882 was a triumph of scientific knowledge and mechanical ingenuity, it had certain limitations: the practical difficulty in utilizing the high speeds necessary for its efficiency; and the fact that the single-wheel impulse turbine could not at this time be made in large sizes; it was limited to about 450 hp. If the turbine were to rotate at slower than ideal speeds, energy would be wasted. Nonetheless, the De Laval turbine had the advantage of simplicity in construction; it was lightweight; and its steam consumption was low. Within its range it was as efficient as any other steam engine, and it was used fairly extensively for driving fans, pumps, and electric generators.

**2. Parsons' Turbine.**—The reaction turbine built by Charles Parsons in England in 1884 proved to be of more general industrial significance than De Laval's, but it was not a greater achievement. Parsons was the first to solve the problems, on a practical scale, of the utilization of the properties of steam and the theory of motions of fluids in the reaction turbine. The first unit built by

Parsons developed 10 hp. and utilized steam at 80 psi. This turbine rotated at 18,000 rpm and was coupled directly to a dynamo. The shaft had 15 gunmetal rings, each having radial slots around its outer edge and set at an angle of 45° to the face. Between these rings were 15 half-rings fitted to upper and lower halves of the casing, and these had similar slots on their internal edges. Steam admitted in the middle flowed through the slots toward each end, where it was exhausted to the atmosphere. Toward the ends of the shaft the slots were deeper and the blades between them longer because there was a gradual decrease in pressure from the middle to the ends. The blades themselves were flat and only thinned at the edges. These fixed and moving blades admitted the steam through fixed guide blades to all the blades of each ring.

PARSONS' ORIGINAL STEAM TURBINE, 1884, SHOWN DRIVING AN ELECTRIC GENERATOR

The Parsons turbine called for scientific knowledge and mechanical ingenuity of a high order. Because of its high speed of rotation, Parsons found it necessary to provide special bearings. Recognizing that the chief loss of energy was in leakage of the steam past the blades, he focused his attention on the best form for the blades, using blades with curved faces in his turbine of 1888. The double parallel flow from the middle to the ends was retained, and he provided an increase in diameter of the drums toward the ends. The efficiency of his turbine was therefore improved. The earlier turbine had required 125 lb. of steam per kilowatt-hour, whereas the later unit consumed only 58 lb. per kilowatt-hour. In 1889 four 75-kw. Parsons units that operated at 4,800 rpm became the first steam turbines to be installed in a public power station.

In 1889 Parsons left his old firm and struck out for himself. Since the firm retained the patents on the parallel-flow turbine, Parsons worked out a new type of turbine having a radial flow outward. This type was demonstrated in 1897 on the famous "Turbina," a ship about the size of a modern torpedo boat. Using three shafts, each capable of developing 700 hp., the ship traveled at a record speed of 34½ knots. In the same year Parsons installed a 150-kw. set in an electric power station at Plymouth, Eng. The early turbines had been noncondensing (*i.e.*, the steam was not condensed but was exhausted to the atmosphere), but, as their size began to increase and economy became more important, they came to be of the condensing type. It was extremely important to pass the steam to the condenser with as little delay or restriction as possible, and in 1899 Parsons patented a form in which the turbine and the condenser formed a single unit.

As it became increasingly evident that it would be advantageous to make the turbine larger, Parsons built tandem units with the high pressure and the low pressure on the same shaft but enclosed in separate casings.

**3. Refinements in Design.**—The Parsons patents gave his company nearly a monopoly, and many engineers turned to removing the limitations of the De Laval single-stage impulse turbine, which involved high-velocity steam expanding in nozzles at one step from the full pressure of the supply to the pressure of the exhaust. It also involved centrifugal stresses set up in the wheels and blades by the high speed necessary for maximum efficiency. Charles G. Curtis of the U.S. introduced his velocity-compounding turbine in 1898. He avoided the limitations of the De Laval turbine by adding rows of moving blades with fixed guide blades to direct the steam on the driving blades. In the Curtis turbine the

blades were so designed that the velocity of steam was reduced by stages. This made it possible to use essentially the impulse principle but to work with high efficiency while operating at lower revolutions per minute. In 1896 C. E. A. Rateau of France combined the impulse with the pressure-compounding principle of Parsons and produced a number of impulse, or velocity, wheels on a shaft separated by sets of blades which in fact were nozzles in which there was a limited drop in pressure. The Rateau turbine reduced considerably the high speed required for a single-wheel impulse turbine.

It was not until 1915 that research was applied to the design of condensers. The old steam condenser usually had been a tank provided with a number of water tubes to provide the largest possible cooling surface. Real efficiency was only the result of chance, and there was no consideration given to the flow of steam over the tubes or to the separation of air at the lowest temperature and separation of water at the highest temperature. The first man to undertake a more scientific design of a condenser was Delas. He arranged the tubes in a series of V's across the condenser, which facilitated the access of the exhaust steam and air to the cooling surface. Because the steam passed from the top to the bottom of the condenser and crossed only relatively narrow bands of tubes, there was only a small drop in pressure. The Delas tubes were also arranged in a diamond pattern, with the long diameter of the diamond at an angle to the vertical so that no tube was directly above another. Thus the drip from the upper tube ran around only a portion of the circumference of the tube just below it, and the area of wetted surface was reduced. There was therefore an increase in heat transfer, since there was no insulating film of water. It was known that small condensers of the older types were on the whole reasonably satisfactory, but larger condensers built on the same design proved much less efficient. In determining the reason for this inefficiency, a group of engineers of the Vickers firm showed that there was a difference in pressure between the top and the bottom of the condenser, and that the way to improve efficiency was to increase the area of approach to the tubes and decrease the length of steam passage between the tubes. In the Vickers condenser the steam enters at the top, flows around the entire circumference, and then flows radially to the centre. The steam condenses on the outer rows of tubes, collects at the bottom of the shell, and is drawn off by a pump. This represents a major improvement over earlier arrangements.

#### 4. Advantages over the Reciprocating Steam Engine.—

Thomas Edison, in developing the first large dynamos, found that they required steam engines operating at 1,000–1,500 rpm, but these speeds were impossible for the larger horsepower units with reciprocating pistons. However, the opposite was true of turbines. As size increased, it was possible to design turbines for lower and lower speeds, and from this fact the steam turbine was quite early married to the dynamo. The reciprocating steam engine, particularly in the larger sizes, vibrated considerably, but turbine vibration was practically nonexistent. In size, the reciprocating steam engine proved to be limited; units of 6,500–7,800 hp. for marine use were about the maximum. But in the space of 30 years the turbine grew from a crude machine of 10 hp. to one embodying hundreds of refinements of design and producing as much as 60,000 hp. in a single unit. It was applied in enormous units to the propulsion of ships and to the production of electric power. Furthermore, its more efficient use of heat energy permitted an economy not possible with the reciprocating steam engine. With the use of superheated steam, higher pressures, and the scientifically designed condenser, the steam turbine assumed essentially the form that it has at the present time.

#### B. THE STEAM BOILER

The development of steam boilers closely paralleled that of steam engines. The steam engines of Watt's day were supplied from a wagon-type boiler. The boiler was set in brickwork with a fire grate underneath, and the hot gases ran in flues along the outside. In the first quarter of the 19th century a variety of boiler types appeared: some were made of copper, some of wrought iron. However, metals of more than  $\frac{1}{4}$ -in. thickness could be handled by only

a few machines and not at all by hand, so that boiler construction limited the pressures which were possible.

The first step forward from these early boilers was the fire-tube boiler with an internal fire grate. One common fire-tube type was the Cornish boiler, which consisted of a long cylindrical shell with a single fire flue passing down its middle, the flue being about one-half the diameter of the boiler itself. Another important type was the locomotive boiler, invented simultaneously in 1829 by Marc Séguin in France and George Stephenson in England. This boiler employed a large number of smaller fire tubes passing through a cylinder filled with water and steam.

**1. Pressure Gauges.**—The earliest pressure gauges usually consisted of mercury in a U-tube that was connected at one end to the boiler, with the other end left open to the atmosphere. However, most of the early engineers depended upon a lift safety valve to blow off at the desired pressure.

The first reliable gauges, still in use today, date from the mid-19th century. In 1849 Eugène Bourdon invented a curved metal tube of elliptical cross section with the free end closed and the fixed end open to the pressure inlet. Since internal pressures greater than external pressures tend to straighten out the tube, this motion passing through a linkage allows the pressure to be read on a dial. In 1851 Schaffer utilized a circular corrugated plate, the movement of the centre of which passed through a linkage and so registered the pressure on a dial.

**2. Feed Water Heaters.**—The drive to increase efficiency led also to the feed water heater, sometimes called the "economizer." If feed water at an initial temperature of 50° F (10° C) was preheated to 100° F (38° C), there was a fuel saving of 6%, and, preheated to 180° F (82° C), there was a fuel saving of as much as 11%. Economizers were widely adopted after 1880 since they were inexpensive, efficient, and particularly useful where fuel was expensive or the installation large.

**3. Stokers.**—In order to produce steam uniformly, a regular and skilful supply of fuel was necessary. The increased size of boilers and increased rates of steam, however, meant not only that the labour of stoking was heavy but the fire grates became so large that the men simply could not throw the coal that far. Automatic stokers were introduced about 1880. Some had a hopper and chamber just outside the fire opening, and a ram pushed forward each delivery of coal from the hopper; some used a vertical ram from below; still others had fire bars on an endless chain that ran on rollers, the fuel being fed from a hopper.

**4. Superheat.**—After the work of Rankine, the advantages of superheat and of dry steam became apparent. Wet steam, the steam taken directly from a boiler, always contains small drops of water. These drops of water do no work; in fact, they actually absorb heat, and in the steam supply for a turbine these drops can have a disastrous effect.

Various attempts were made to dry the steam. A number of early steam dryers had varying degrees of success, but none of them was sufficient for the large steam turbine. Instead, the process of superheating the steam proved to be the most efficient and economical means of securing dry steam. The principle was to superheat the steam on its way from the boiler to the engine by passing the steam through narrow coils of tubing in the flue uptakes of the boiler. As a result the drops of water evaporate, the temperature increases without change in pressure, and therefore a smaller weight of steam fills the cylinder up to the point of cutoff. Initial condensation is thus eliminated, and for turbines it reduces friction caused by the water drops on the blade and parts of the turbine.

Tentative experiments begun in 1850 used superheat at about 100° F (38° C) above the temperature of the steam in the boiler but the amount of superheat soon rose to 300–400° F (150–200° C). It was found that steam consumption was about 10% less for each 100° F of superheat. By 1895 it was in general use, and modern installations often have a special superheating boiler for supplying turbines. See further **BOILER**.

#### XI. THE PRODUCTION OF METALS AND ALLOYS

By the 18th century steel was being made by heating wrought iron in a furnace with charcoal, then bending, heating, and rolling.

eral times to produce what was called shear steel. Because this process was expensive and possible only on a small scale, steel continued to be used only for knives, weapons, and tools. In 1740 Benjamin Huntsman of Sheffield, Eng., produced cast steel by heating a pure Swedish iron in a crucible with charcoal. Though Huntsman's crucible-cast steel proved that steel parts could be made in many copies without the labour of wrought iron, its main significance was that its exceptional hardness made it suitable for metalworking tools.

In 1850, then, cast iron, wrought iron, and cast steel were available, but only to a limited extent for engineering purposes. The revolution in steel processing over the next 50 years brought about a tremendous increase in the capacity and speed of production, in the cheapness and ease of manufacture, and, perhaps most important of all, in the control by which these materials were available in known and certain characteristics.

**1. The Hot Blast Furnace.**—One very important improvement remained to be made for the blast furnace—the invention of the hot blast. In 1825 it was generally thought that the colder the air in the blast of the furnace, the more efficient it was. Incredible as it may seem, men went to some trouble to cool this air, passing it over cold water or through pipes encased in ice. In 1828 J. B. Neilson of Scotland developed a method of preheating the air blast before its entry into the furnace, and in 1829 it was tried at the Clyde Ironworks. With the air blast heated to 300° F (150° C), the coal required to produce a ton of iron dropped from 8 to 5 tons.

By 1833 Neilson was using air blasts 600° F (315° C), with a further reduction to 2½ tons of coal required per ton of iron. Using a tubular cast-iron oven to preheat the air to his blast furnace, Neilson's process won immediate acceptance.

The heat, as Neilson used it, was supplied directly by solid fuel, but Faber du Faur suggested using the waste gases of the blast furnace itself. In 1860 this hot blast was improved by E. A. Cowper, who used a regenerator, a wrought cylinder 60 ft. in height and 28 ft. in diameter, that had a circular flue extending from the bottom to the top. The rest of the interior was filled with loose firebrick; after 1875 these bricks were arranged in rows, with alternate bricks projecting along vertical channels. Combustion of the air and the waste gases of the blast furnace, which enter at the bottom, heats the bricks red hot as the exhaust goes out the chimney. The inlet and exhaust valves are then closed, and the cold air is admitted as the hot blast goes to the furnace via the hot blast valve. Since continuous hot-air blasts are needed for the blast furnace, there are usually two or four of these regenerators per furnace.

The Cowper stove (*q.v.*) produced two important results. First, with the hot blast, iron ores could be utilized that were not possible with the cold blast. This proved to be the foundation of the Scottish iron industry. Second, anthracite coal could be used, and this was the foundation of the Pennsylvania iron industry.

**2. Bessemer's Converter Steel.**—The blast furnace could now turn out good pig iron rapidly and cheaply from almost any ore and with almost any fuel. But the brittleness of cast iron limited its use. Wrought iron and steel were being produced, but the process was slow, costly, and uncertain. The problem was how to produce steel from cast iron easily and cheaply. A solution occurred to Henry Bessemer of England. He used an air blast blown through

molten pig iron to burn out all the silicon and carbon. At first he tried a mixture of air and steam, then air alone. He discovered that the combustion of the impurities in the iron produced a temperature high enough to make the steel as liquid as water and that in half an hour he could convert cast iron into a wrought iron of better quality than any then available. In Bessemer's fixed vertical converter of 1855, there was loss of heat while the molten metal was run into and discharged from the converter. A newer type patented in 1860 contained about 49 ½-in. holes in the base through which air was blown. Iron melted in a furnace above the level of the converter was run into the converter while it was in a nearly horizontal position. The converter was slowly returned to a vertical position by hydraulic means, and an air blast of 15 psi was turned on. When all the impurities were burned out, the blast was shut off and the converter was returned to its horizontal position. Bessemer could then add definite quantities of cast iron of known composition. The converter, then brought upright, had the blast continued until all the additives were thoroughly mixed in. The converter was again brought horizontal, the blast shut off, and the steel run out through a wrought iron trough into molds.

Chemically the carbon and silicon in the pig iron were oxidized at the increased temperature, with the air blast supplying the agitation and the oxygen. After about 20 min. all the carbon was burned up and the iron itself was beginning to oxidize. Iron oxide, silica, and earthy substances formed a fusible slag, but the liquid iron could be run out at the tap hole. In theory, if the draft were stopped at the correct point, iron of any desired carbon content could be made, but in practice this was impossible, and so the run was burned to completion and the desired carbon added in the amounts specified.

Bessemer's process at first proved troublesome. Having sold his process rights to a number of ironmasters who tried it out and found the results variable and often unsatisfactory, Bessemer was

THE BETTMANN ARCHIVE

MANUFACTURE OF STEEL, USING BESSEMER CONVERTERS; FROM AN 1875 ENGRAVING

much abused. In a subsequent investigation he determined that the trouble was in the variations of pig iron used by the various firms. Chemical tests showed that Bessemer had by sheer luck used a pig iron low in phosphorus and sulfur but that the other iron men had used a pig iron high in these materials. Bessemer persuaded the disappointed ironmasters to sell their rights back to him, a move that was the basis of Bessemer's later enormous fortune. Upon further examination Bessemer found that the original ore from which these pig irons had come was low in phosphorus. The ques-

tion was how did it get into the pig iron? Since the iron makers had used a kind of cinders as a flux in a puddling furnace, Bessemer tried to get pig iron from the same ores without the use of this flux, and the result was a pig iron low in phosphorus that is still known as Bessemer iron. Now the results were satisfactory, especially after Robert Mushet had suggested the use of spiegeleisen, a pig iron containing about 20% manganese. With his partners Bessemer then set up the firm of Henry Bessemer & Company in Sheffield, Eng. The demand for a metal harder than wrought iron and less brittle than cast iron was enormous, and, in the 24 years that the partnership existed, the owners had a return of 81 times their original investment. Bessemer almost immediately undersold his competitors by 40 to 50%. Bessemer steel replaced wrought iron for the ever-expanding railroads and for construction work because of its higher tensile strength. It was soon used for boilers, piston rods, connecting rods, and crankshafts. It was a new and stimulating factor in engineering practice. Bessemer had, in fact, laid the foundations for two most important advances: first, for the provision of steel of known and uniform characteristics; and second, for the use of alloy steels and the heat treatment made possible by the use of these alloys. The importance of Bessemer's work is given by these figures: in 1855, the year of Bessemer's invention, approximately 50,000 tons of steel were produced; in 1898, the year that Bessemer died, 4,660,000 tons of steel were produced. Bessemer's success attracted many men to the problem of steel production. Among the few who succeeded were the Siemens brothers, whose process ultimately supplanted the Bessemer process as the leading method of steel manufacture.

**3. The Siemens Process.**—The German-born Siemens brothers belonged to a family famous for its scientists and inventors. William Siemens and his brother Friedrich became interested in the new theories and applications of heat and energy. In 1856 Friedrich Siemens applied the regenerative heating principle to the furnace. The two brothers designed a number of furnaces on this principle, but as the furnaces increased in size they encountered more and more difficulties. Finally they designed a system in which the fuel was converted into a gas before it was burned. In 1861 William Siemens was issued a patent for that principle and in the same year constructed a furnace having separate gas producers and firebrick regenerators. Neither principle nor the gas furnace was new, but the Siemens brothers were the first to make it commercially successful. An important advance occurred when Émile and Pierre Martin of France used a furnace of this type in 1864 to produce steel from pig iron and steel scrap.

The advantages of the Siemens process were most important. It proved to be very efficient, for the heat loss was very small, but more importantly, the flame could be kept perfectly steady for any length of time. Furthermore, the flame could easily be made to oxidize, or reduce, or remain neutral. In short, the Siemens brothers not only increased the efficiency but, what was more important, introduced control.

The use of the regenerator principle to manufacture steel made possible the Siemens open-hearth method (1861), in which pig or cast iron and scrap are melted in an open-hearth furnace to produce molten steel. The hearth is a basin-like bottom of a reverberatory furnace, 40 ft. long by 15 ft. wide and about 2 ft. deep ( $12 \times 4.5 \times 0.6$  m.), which is lined with heat-resisting materials. Natural gas or sprayed oil is mixed with air for combustion, and the gas fuel is preheated by the regenerator. When a high temperature is reached, the carbon goes off as an oxide, and the steel looks as though it is boiling. The silicon, phosphorus, and sulfur oxidize and combine with limestone or spiegeleisen to form a slag that rises and can be removed from the surface. The Siemens process proceeds much more slowly than the Bessemer process, and it permits testing for the desired carbon content. It can thus be stopped at any desired point, and the molten metal can be run into molds or ladles.

Though the Bessemer process had the advantage that no fuel was required to produce the steel from pig iron, the Siemens process permitted better control and produced a larger and more uniform yield from a given weight of pig iron. Bessemer steel is still used for steel rails, but Siemens, or open-hearth,

steel has a much wider application (e.g., bridges, general construction, plates for ships, etc.).

**4. The Basic Process.**—The third important process in the era of cheap steel is the basic, or Gilchrist-Thomas, process. Bessemer had used a siliceous lining in his converters that had produced an acid slag and therefore did not remove the phosphorus in the original pig iron. The ultimate solution was the work of Percy C. Gilchrist, a chemist, and his cousin Sidney G. Thomas, a metallurgist. Their solution was to replace the acid lining of the furnace with a basic, or alkaline, lining for both the Bessemer and the Siemens process and then during the operation to add quicklime. Though Thomas announced the method in 1878, it attracted very little attention, until in the following year it was publicly demonstrated.

This method was adopted even more rapidly than had been the Bessemer process. The results of the basic process were most important. First, the phosphorus-bearing ores, the most widespread and the most plentiful of all the ores, became usable. Second, the open-hearth process generally replaced the Bessemer process for basic-steel manufacture.

With these three steel processes in use, steel was abundant and easily available from pig iron. Steel production was cheap and rapid, and pig iron from almost any ore was usable. With adequate means of control, it was possible to make steel not only of any carbon content, but of almost any desired alloy.

**5. Alloy Steels.**—Alloy steels go back to 1871 with the work of Robert Mushet and his tool steel, in which chromium and tungsten were added to steel to produce a material that attained its maximum hardness if cooled in the air. After 1880 steels containing nickel, chromium, or both were used, but until 1910 they were used almost exclusively for guns and armour plate.

The first commercial departure in alloy steels from guns and armour was made with tool steel. In 1880 there began 26 years of research on cutting metals by Frederick W. Taylor and Maunsel White of the Midvale Steel Corporation. They produced high-speed cutting steel that was immensely superior to the carbon steels then in use. Previously Mushet's tungsten steel had been hardened for tool steel by heating to about 1,500 to 1,550° F (815 to 845° C). Taylor and White, however, found that if this tool steel were heated to a point just below where it would crumble if it were touched, that is, 1,900 to 2,012° F (1,040 to 1,100° C), and if it were allowed to cool steadily, there was a great increase in toughness and hardness. This process marked the beginning of a new era in tool steel. Later, tool steel was made from other alloys, such as cobalt, molybdenum, and vanadium, and some tool steels were not really steels at all, e.g., Stellite, in wide use from 1900 to 1925, composed of 55% cobalt, 15 to 25% tungsten, and 15 to 25% chromium.

Since 1910 alloy steels have had a variety of uses, e.g., engines and machinery, automobiles, bridges, and locomotives. By the use of alloys it has become possible to control or increase the tensile strength of steel, as well as its hardness, toughness, and its resistance to corrosion. Of course, heat treatment has added another dimension to steel processing.

**6. Nonferrous Metals and Alloys.**—For many centuries copper, zinc, tin, and lead were known as metals. Bronze, an alloy of copper and tin, was produced in ancient times, as was brass, an alloy of copper and zinc. Gunmetal, a hard bronze of eight parts of copper and one of tin, was used before steel for cannon and is still in wide use. Antimony, which was also known from early times, taken together with lead and tin was used in type metal; it was also used in Babbitt and other antifriction metals.

Though aluminum is one of the most widely distributed of the metallic ores, it was not until 1825 that Hans Christian Ørsted isolated the metal by working with potassium. From 1827 to 1833 a few chemists obtained a small amount of aluminum in the form of a gray powder, principally by the action of pure sodium on sodium aluminum chloride, a very expensive process. Then almost simultaneously in 1886 Charles Martin Hall, in the United States and Paul L. T. Héroult, in France, utilizing the electric furnace and a solution of aluminum oxide in fused aluminum sodium fluoride, were able to obtain pure aluminum. Its properties permit

it to be cast, wrought, extruded, drawn into thin wire, rolled into thin sheets, welded, and even soldered for a remarkable variety of uses. It can also be alloyed with copper, silicon, zinc, manganese, nickel, and magnesium for most industrial applications.

**7. Metallurgy Becomes a Science.**—Prior to 1860 most metallurgical processes were looked upon as a complete mystery, and the practical man depended upon his rule of thumb. The result was varieties of cast iron that appeared gray, white, and mottled. Steel alloys and a host of nonferrous alloys were produced by mechanical or heat treatment but they had been produced largely by accident or by trial and error in the first place.

The development of a scientific theory of metallurgy began effectively with H. C. Sorby in 1861. Sorby, a geologist, was familiar with the technique of grinding down thin slices of rocks and examining their structure under a microscope. Applying this to metals, he polished a thin piece and then either etched it with an acid or other reagent or permitted it to oxidize by air. Sorby found that the metals had a pattern and a structure and that some of the parts were attacked while others were not. He also discovered that the patterns of their structure were characteristic of the metal. Sorby worked only on iron and steel, but produced some of the most beautiful photomicrographs that have ever been seen. However, his work attracted very little attention. Only about 1880 did metallurgists in France, Germany, and England begin to take up his work. By combining Sorby's methods of examination with chemical analysis, particularly of alloys, they further extended the correlation of microscopic structure with the mechanical and physical properties of the metal. This resulted in a tremendous accumulation of information, such as rates of cooling from the molten condition, rates of expansion, rates of electrical conductivity over wide ranges of temperature, etc.

A genuine theory and science of metals and their alloys developed rapidly with the application of J. Willard Gibbs's phase rule (1876), which enabled a clearer understanding of the formation of the various components of alloys, and, after 1912, with the work of William H. Bragg and his son William Lawrence Bragg, who developed an X-ray analysis technique for the study of crystals.

After 1890 the theories of hundreds of alloys of nonferrous metals were worked out and the foundations laid for heat treatment of nonferrous metals, the aim being usually formation and fixation of particular compounds or solid solutions or altering the sizes of the grain. Hardness and strength of both iron and steel and the nonferrous metals usually are associated with a fine-grained structure, but consideration must also be given to properties desirable for rolling or drawing and for resistance to high temperatures and to corrosion. Since 1900 metallurgists have solved problems of increasing importance, such as high stresses and high temperature, to meet the demands of industry and research. These problems became increasingly important with the introduction of jet-powered aircraft, nuclear power, space exploration, and deep-sea research, all of which depend upon the metallurgist for a variety of new and reliable materials.

## XII. DEVELOPMENT OF THE INTERNAL-COMBUSTION ENGINE

Though the advance of steam power led to installations of greater and greater horsepower, there was also a need for engines of less horsepower. Many factory operations were too light for steam power, and the steam engine was too costly. There was also a need for engines of greater flexibility and lighter weight, especially for land and air transportation. The result was the development of the internal-combustion engine, which became most significant with the discovery of petroleum in quantity in 1859. See INTERNAL-COMBUSTION ENGINE.

### A. GAS ENGINES

**1. Early Inventions.**—The first attempt to derive power from an internal-combustion principle had been made in 1680 by Christiaan Huygens and again in 1690 by Denis Papin. Both men expended a small amount of gunpowder in a large cylinder, expelling the air through check valves. When the resulting gases were cooled,

a partial vacuum was created so that atmospheric pressure pushed down on the piston and did work. Significantly enough, both men utilized atmospheric pressure pressing against a vacuum created by the condensation of gases, a principle that paralleled the development of the steam engine in its early stages, as in the work of James Watt.

The first real internal-combustion engine was used by Robert Street in 1794 to raise water. In the motor cylinder Street used a lever to connect the piston to a pump. Building a fire at the base of the cylinder, he evaporated a few drops of turpentine. The piston was drawn up, and air was admitted and mixed with the vapour. Then a flame was inserted in a touchhole and the mixture exploded. This pushed the motor piston up, forcing the piston of the pump down.

In 1820 William Cecil experimented in England with a heavy piston and a cylinder, the piston being lifted by the explosion of a mixture of hydrogen and air. Then the piston fell under atmospheric pressure and did work. With 60 rpm, regular explosions consumed 17.6 cu.ft. of hydrogen per hour. The device proved to be very noisy, but Cecil is of importance because he was the first to measure the pressures produced inside the cylinder.

By 1823 Samuel Brown had produced the first practical engine operated from gas. He also used a gas explosion to obtain a vacuum. A flame in the cylinder was used to drive out the air, and the flame then was extinguished by a water jet. Brown had in fact several cylinders operating on a crank shaft, and by 1826 his engine was successfully applied to a carriage. In 1827 one of his engines drove a 36-ft. boat that traveled at 7 knots, and in 1832 another engine was installed at Croydon, Eng., for raising water.

W. L. Wright in 1833 was the first to apply the explosion of the air-and-gas mixture to the piston on the working stroke, and his double-acting engine gave an impulse every half revolution of a crank shaft. The gas and air were supplied from two reservoirs by separate pumps at low pressure, and the mixture entered spherical chambers at each end of the motor cylinder. An explosion was produced by inserting a flame through a touchhole, and the combustion products were ejected through exhaust valves. Both cylinders and piston in Wright's engine were surrounded by a cooling water jacket.

In 1838 William Barnett invented the compression system that continues to be used in internal-combustion engines. Its basic principle was to compress the explosive mixture before ignition either by using pumps in separate receivers and then letting the gas mixture, controlled by a piston valve, flow into the cylinder or by drawing the mixture of gas and air into the cylinder by means of pumps and using the mixture to displace the exhaust gases. Compression, then, was partly by pumps and partly by the cylinder piston. In both types of engine, however, ignition took place at dead centre, and the piston therefore got the full impulse of the whole working stroke.

Barnett is also significant for an ingenious ignition device, called the "Barnett Lighting Cock," which he introduced as early as 1832 and which remained in use until 1892. This was most important for the development of the gas engine until an electrical firing system could be adequately developed.

After Barnett, progress with gas engines slowed down until 1859 when two Italian engineers, Eugenio Barsanti and Felice Matteucci, introduced a gas engine of some importance. It embodied a tall cylinder and a heavy piston. The gas-air mixture was admitted and fired by an electric spark, and the resulting explosion forced the piston up. The piston rod was a rack that engaged a pinion at the end of the stroke. A partial vacuum plus the weight of the heavy piston actually did the work. This engine required a heavy flywheel for continuous application of full power. It was noisy and mechanically an outrage, but it had certain theoretical advantages: first, a very wide range of expansion; second, low gas consumption.

The early experimenters with the gas engine found a rather limited fuel supply for their engines. Since gas was needed in quantity, hydrogen and turpentine clearly would not do, and the only other fuel available was town-lighting gas. In the 1790s, however, William Murdock introduced the coal gas process, and after 1820 the considerable development in England of gas for lighting per-

mitted some experimental advance in the internal-combustion engine. However, the production of petroleum in quantity after 1859 provided what was to become the basic fuel for the internal-combustion engine, and the time was ripe for development of an engine of real commercial value.

The first commercially significant internal-combustion engine, produced in 1860 by J. J. E. Lenoir, resembled externally an ordinary high-pressure steam engine, except that the valve systems admitted both gas and air and discharged the products of combustion. Lenoir's first engine, of 3 hp., had a flywheel that impelled the piston on the first part of the stroke. This drew in a mixture of gas and air at atmospheric pressure, and cutoff occurred. When the electric spark fired, the resulting explosion propelled the piston to the end of the stroke. Lenoir made extravagant claims for the efficiency of his engine, stating that an engine of 1 hp. could operate for 12 hr. on 100 cu.ft. of coal gas. Had that been true, it would have operated at about one-half the cost of similar power from a steam engine. Actually the Lenoir engine required about three times this amount of fuel and was really uneconomical as far as fuel consumption was concerned. But the Lenoir engine worked well, and it was sound from an engineering point of view; it was smooth in action, with no shock of explosion, and the cost of construction was favourable as compared with steam engines of the same power. By 1865, 400 Lenoir engines were in use in France, and soon 1,000 were in operation in Great Britain. They were widely used for low-power jobs, pumping, printing, etc. They proved to be quite durable; some were in perfect condition after 20 years of continuous operation. The Lenoir engine was also successfully applied to an experimental road carriage and to a boat, both of which used a hydrocarbon similar to gasoline.

**2. Theoretical Development.**—The theoretical development of the internal-combustion engine began with vague and often incorrect notions of gaseous explosions. Lenoir believed that the power was provided in a sudden blow, resulting from a rapid rise in pressure followed by an equally rapid fall and that therefore better economy could be achieved if the explosion could be slowed down. He therefore tried to inject sprays of steam or water to avoid explosion and produce burning. R. W. Bunsen showed that actually the opposite was true and that the explosion of gas and air was really a kind of continuous combustion. G. A. Hirn showed that the heat evolved in the explosion was only a fraction of the total heat produced and that the rest was produced during the expansion of gases. Thus expansion was not to be avoided but induced.

The next step was to study the advantages of a preliminary compression of the gas-air mixture. In 1861 G. Schmidt undertook the study of economy in the gas engine. He found that if he compressed the gas-air mixture to three atmospheres before it entered the cylinder, there was a great expansion and transformation of heat, and so he provided in his experimental engine compression pumps that were worked by the engine itself. In the same year François Million in France went further and provided separate pumps for compression of the air and the gas in a reservoir. The motion of his piston drew in a charge of the mixture under pressure, and electric-spark ignition followed. Thus the whole of the piston stroke could be powered by explosion, rather than only part of it. With the work of these two men the advantages of compression were firmly established.

Further parallelism of the development of the internal-combustion engine with that of the reciprocating steam engine occurred when Alphonse Beau de Rochas studied the influence of two factors on the economy of the gas engine using compression: first, the volume of the hot gases employed; and second, the extent of the surfaces exposed. The results of his studies, published in 1862, were very similar to Rankine's theoretical and experimental studies of the steam engine in 1859. De Rochas found that certain conditions must be at a maximum for economy: first, maximum cylinder volume for the least possible cooling surface; second, maximum rapidity of expansion; third, maximum amount of expansion; and fourth, maximum pressure at the beginning of expansion.

De Rochas was also responsible for the four-stroke cycle, which

has since formed the basis of gas- and oil-engine practice. It was 14 years before his theoretical results were fully accepted. From the introduction of his theories in 1862 until the appearance of an effective Otto engine in 1876, De Rochas' own designs had ignition difficulties, as did most engines of the time. Lenoir had also experienced trouble with his electrical ignition, but he significantly suggested that the gas-air mixture could be ignited by a higher temperature produced by compressing the mixture to one-fourth of its volume. This was essentially the principle used later by Rudolf Diesel. Although De Rochas never built an engine, he laid the theoretical basis for the work of the German engineer Nikolaus A. Otto, who in 1877 patented his famous "silent gas engine." Otto's engine, based upon his independent invention of the De Rochas compression cycle, was superior in workmanship, and detail to all previous engines, and it also embodied an efficient ignition system. Otto did for the four-stroke-cycle principle what Lenoir had done for his predecessors, that is, he embodied all that had gone before in a practical precision engine. The Otto engine was quite economical, operating on 20 cu.ft. of gas per horsepower hour. Although the engine was a great engineering success, Otto himself was rather weak on theory. He accepted Lenoir's idea that engine economy was due to slow expansion of the gases in the cylinder, and he associated this with the curious phenomenon called "stratification." Actually its efficiency was due to compression, which Otto himself thought was of no significance. Nonetheless, the Otto engine was as great a landmark in the history of the internal-combustion engine as was Watt's double-acting engine in the history of the reciprocating steam engine, for it proved to be the basis of all later development. The small horsepower engine brought about a revolution in road transportation, and it also assisted the growth of the small factory, in which the use of more powerful engines was not economical.

**3. Mechanical Improvements.**—In 1879 an important development occurred with the appearance of the two-cycle engine, which could produce more power for a given size of engine and could give more uniform speed because there was a working stroke for every revolution of the crank. Introduced by Dugald Clerk, the two-stroke engine used a pump at the side of the main cylinder to deliver the explosive mixture when the piston reached the end of the backward stroke, and exhaust ports at the front end of the cylinder opened as the piston reached the end of the forward stroke. However, it did not give twice the power of the four-cycle engine, as one might expect, because the admission valve was open for a shorter portion of the stroke and therefore the charge was smaller. A few engines were made, but the two-stroke engine did not come into use largely because the demand for the large gas engine had not arrived, and it was 20 years before Körting revived the Clerk cycle for large powers. However, in 1891 Day substituted an enclosed crankcase for the charging pump in the small two-stroke engine. Day built several types of gas engines: one, a two-port engine, had a single valve; and another, a three-port engine, had no valve, all of the ports being opened and closed by the action of the piston. This latter type is not used in modern gas engines but it does appear in oil or gasoline engines. The two-port type is found in the Bollinder marine oil engine, commonly used in British trawlers.

After 1912 there was little change in gas engines smaller than 400–500 hp. The larger sizes became standardized rather early and were made by mass production. Many of the larger sizes came to be made by combining smaller units of the vertical type into multicylinder engines.

**4. Fuel Supplies.**—New sources of fuel supply for gas engines became available after 1860. Siemens, needing gas for his open-hearth steel furnaces because no solid fuel could give the required temperature, developed producer gas by burning coke in a limited supply of air. In 1878 Dowson developed a plant for making this gas, and by 1881 producer gas was used to drive a 3-hp. Otto gas engine. The water-gas process, by which steam was passed over red-hot coke to produce carbon monoxide and hydrogen, was an intermittent process because the steam cooled down the coke and air had to be admitted at intervals, but by 1889 Ludwig Mond introduced the method of admitting air and steam to the hot coke so

that the result was a continuous process producing a mixture of producer and water gas. However, it soon became apparent that if coal scraps were used instead of coke, the by-products of tar and ammonia would reduce the cost, since the ammonia could be converted into ammonium sulfate, which is useful as a fertilizer. Supplies of gas such as this enormously enlarged the possibilities of the gas engine, and its size rose from 100 hp. to as much as 500–600 hp.

There were also improvements in the ordinary gas producers. Instead of drawing in air by a fan or blowing in air and steam, the producer was hooked directly to an industrial gas engine, and the engine sucked in gas from the producer as fast as it was required. There was therefore a pressure inside the producer less than atmospheric and hence less danger of carbon monoxide in the air of the producer house. This method not only reduced the cost of gas production but it also made possible the use of almost any combustible material for the fuel-bed (e.g., wood waste, sawdust, bark, coal dust, coconut shells, sugar cane refuse, cottonseeds, or rice husks). This meant, then, that the gas engine could be used to provide power for preliminary manufacturing processes on farms, plantations, forests, and mines, and in places where cheap coal was not available. This had enormous economic and social consequences.

A still further supply of gas became available in the waste gases from the blast furnace. In 1892 B. H. Thwaite suggested that these waste gases, which had previously simply been burned, could be used. In 1895 the Glasgow Iron Company adopted this method, and its use spread rapidly in Germany and the United States.

The increase in size of the gas engine made possible by cheaper fuels led to two new mechanical problems. It proved difficult to construct the large cylinders free from strain because of unequal cooling in the mold, and the cylinders were therefore not capable of withstanding the stresses set up by large temperature gradients in the material when the engine was in operation. Also, it was difficult to keep the piston cool. For small engines the water jacket was effective, but for larger engines it was necessary to design a hollow piston cooled by the internal flow of water that was supplied by a jointed tube, one end of which could follow the motion of the piston.

## B. GASOLINE ENGINES

The success of the gas engine led to many attempts to utilize other fuels. In 1884 Gottlieb Daimler passed a current of warm air through a definite thickness of gasoline to produce a mixture of gasoline vapour and air, which was ignited in the cylinder by a hot platinum tube. His engine, which had a four-stroke cycle and an enclosed crankcase, used splash lubrication. The admission valve was opened by suction, the exhaust valves by a cam. Previously, internal-combustion engines had been of slow speed, usually less than 200 rpm, and of heavy construction, about 1,000 lb. per horsepower hour. But by 1886 Daimler had been able to construct a gasoline engine operating at 800 rpm and having a weight-to-horsepower ratio of only 88 lb. per horsepower. Though both the speed and the lightness of the engine were important, the use of a liquid fuel was the crucial solution to the difficulty of applying the internal-combustion engine to road transportation.

Daimler, too, had difficulties with fuel. Gasoline was then a laboratory material, and there were wide variations in the available fuel. Furthermore, his surface-type carburetor tended to evaporate the lighter fractions before the heavier fractions, and therefore the composition of the fuel changed as the engine ran. By 1893, however, Wilhelm Maybach had produced a carburetor that utilized a needle valve and a float. The gasoline passing through a nozzle under the suction of the engine and mixing with the air through a fine gauze at increased velocity produced an excellent mixture.

Daimler applied his engine only to boats and canal barges. Later others applied them to automobiles and aircraft. These engines were nearly always of the vertical type, although some V and radial types were produced quite early. The cylinders were at first air-cooled, but later they were nearly always water-cooled, either through natural circulation or by means of pumps.

In the late 1890s and the early 1900s the gasoline engine prof-

ited from several improvements. The ignition system was improved first with the use of the induction coil and the dry battery and then with the introduction of the magneto. A number of different valves were tried—the rotary valve of the Corliss type, the piston valve, poppet valves, etc. Fuels such as benzene and kerosene were tried, but gasoline predominated, especially after 1914 through the development of various cracking processes. The main development, however, was further advance in lightness through the use of aluminum and its alloys. Next was greater reliability through improved design, materials, and workmanship, and third was cheaper engines made possible by mass production.

## C. OIL ENGINES

**1. Priestman and Stuart Engines.**—The medium oil engine used a fuel with a specific gravity of about 0.8 that was similar to kerosene. This development began with Priestman in 1884. In his engine, oil was sprayed by air pressure into a vaporizer that was heated by a lamp. The resulting fuel was drawn into a cylinder mixed with air, compressed, and fired by a hot tube. Once the engine was running, the lamp could be removed since the vaporizer was adequately heated by the hot exhaust gases.

There were a number of oil-engine inventors after Priestman, the most important being Akroyd Stuart. In his engine, called the Hornsby-Akroyd engine, no separate vaporizer or ignition was required. To start the engine a portion of the cylinder was heated with a blowtorch. Air was drawn into the cylinder by suction, and oil was sprayed in by a small force pump. The return stroke of the piston forced the air into the hot end of the cylinder, and ignition took place by the heat of compression. The heat of combustion kept the cylinder end at the proper temperature, and no blowtorch was required after starting. This engine had no coils, dry batteries, accumulators, magnetos, or spark plugs, and so was quite simple. Fuel consumption in the early engines was about one pint of kerosene per horsepower hour, but this was soon improved to about half a pint.

**2. The Diesel Engine.**—Although Rudolf Diesel patented his engine in 1892, he was unable to construct an engine until 1897, and it was some years before a commercially successful model was developed. Unlike the Hornsby-Akroyd engine, this four-stroke-cycle engine did not vaporize the fuel; the air, but not the fuel, was compressed by the piston to pressures of about 500–600 psi. This compression of the air resulted in temperatures of about 1,000° F (538° C). The fuel was fed in at a rate such that combustion took place at nearly constant pressure. The diesel engine was usually vertical and of rather heavy construction. It used rather heavy fuel with a specific gravity of from about 0.83 to as much as 1.1. Originally the fuel was forced in by air at 1,000 psi. It was, however, costly to compress the air, and a method of solid injection was invented by James McKechnie in 1910. In this the fuel was admitted through a needle valve at pressures of about 4,000 to 7,000 psi produced by a small pump.

From the beginning the greatest advantage of the diesel engine was its efficiency. At first it was built in small sizes, but by 1912 single vertical engines of 50, 80, or 120 hp. of the four-stroke cycle were built, and these units were combined to give 750 hp. However, some of the same difficulties experienced by the large gas engine had to be overcome; in fact, these difficulties were greater because of the higher temperatures and pressures in the diesel engine. Smoother operation was made possible in the four-stroke engine because of multiple cylinders, and greater power was obtained by introducing double action with enclosed cylinders, and two-stroke engines. Both of these, however, required cooling the piston with either water or oil. Some double-acting, four-stroke engines were built before 1915, and they became well established after 1925. The two-stroke diesel engine was similar to the two-stroke gas engine, and it worked equally well in either direction. It could be reversed by letting the engine nearly stop and then admitting compressed air before the piston reached the end of the stroke.

**3. The Semidiesel Engine.**—The economy and reliability of the diesel engine led to efforts to combine its principles with those of the Hornsby-Akroyd engine to produce a lighter engine of

lower cost, with equally high efficiency. The result was the semi-diesel engine, which could use a fuel similar to that of the diesel engine. Both horizontal and vertical types were built, usually of less than 600 hp.

#### D. THE GAS TURBINE

The gas turbine was an attempt to achieve the advantages of the internal-combustion engine without the complications associated with reciprocating motion. It operates by directing a continuous stream of hot gases against the blading of a turbine rotor.

The success of the steam turbine led to attempts to apply its principles to a gas turbine in the early 1900s. R. Armengaud and C. Lemale of France built the first successful unit in 1903. It consisted of a three-cylinder multistage compressor and a combustion chamber in which liquid fuel and air from the compressor were burned. The products of combustion, cooled somewhat by water injection, were then expanded through an impulse turbine wheel. Though its efficiency was only about 3%, it was a significant achievement.

In 1908 M. Karavodine built a 2-hp., 10,000-rpm unit with four combustion chambers that directed their hot gaseous products in sequence against a simple De Laval impulse turbine wheel. A gas turbine was also developed by Hans Holzwarth of Germany, who began a series of tests in 1905. He used a constant-volume combustion chamber in which fuel and air were introduced under pressure. After ignition, the pressure was increased about  $4\frac{1}{2}$  times, causing a valve to open for passage of the hot gases into nozzles directed against the turbine blading.

The modern constant-pressure combustion gas turbine is the work of many individuals. Perhaps the most prominent was Sir Frank Whittle of England, who in 1930 developed a jet-propulsion engine with a blower-type compressor that was operated by a gas turbine. Further development during World War II brought about a new era in air transportation.

### XIII. ELECTRICAL ENGINEERING AND ELECTRONICS

**1. Beginnings.**—Until the last quarter of the 19th century technology was dominated by the mechanical and the civil engineer, but from about 1870 electrical engineering came to have greater and greater importance, and after 1925 electronics became the leading field of technological advance.

The growth of electrical engineering was in marked contrast to that of mechanical and civil engineering, which had a long history of practical achievement based largely upon empirical methods derived from accumulated experience and with only limited applications of the results of pure scientific research. But electrical engineering was made possible only by the purely scientific studies of Franklin, Faraday, Ampere, Ohm, Oersted, and Henry. The basic principles of electricity discovered and formulated by these men excited the imaginations of inventors the world over, though electrical engineering, too, went through a brief period of empirical advance. For example, Thomas Davenport, of Vermont, in 1834 devised the first practical electric motor, with an efficient design based upon a rotating armature, and Henry's strong electromagnets found practical application in an ironworks in New York in 1831. In 1860 Antonio Pacinotti invented the basic direct-current dynamo. Ten years later Zénobe Théophile Gramme of Belgium had in operation the first commercial dynamo, thereby launching the age of electric power.

Yet when Nikola Tesla, in the United States in 1887, produced his "polyphase motor" to make possible the widespread use of alternating current, empiricism was not enough, and he had to apply the scientific principles of electricity to solve his technical problems.

**2. Rise of Electrical Power.**—The first phase of the electrical industry centred on sources of limited electrical power—dry cells, accumulators, and wet batteries. These were adequate for certain purposes, such as Samuel F. B. Morse's telegraph of 1837 and Alexander Graham Bell's telephone of 1875. Both inventions grew out of a long preceding series of experiments, and both were made almost simultaneously by other men, but Morse and Bell provided the basic forms that have continued to the present day.

Electrical engineering would have been of only secondary importance if it had had to depend only on these limited sources of power. Crucial to its development were the inventions of the electric dynamo, the electric motor, and the electric transmission line. These produced a revolution in the use of power, for they led ultimately to great hydraulic and steam turbines capable of producing hundreds of thousands of kilowatts of electrical power. The steam turbine, with its far greater efficiency in the use of oil, coal, and now atomic energy, produced so much power that it could not possibly be used at the site—only electric transmission lines and electric motors of any desired size could literally electrify industry.

But all this did not come about at once. In 1831 Faraday had discovered the basic principle of the dynamo. In 1832 Hippolyte Pixii applied Faraday's results to a working dynamo that produced alternating current. In the following year he was able to generate direct current using brushes and a commutator. But these devices were only experimental and depended on the limited capacity of permanent magnets. In 1845 Charles Wheatstone showed that electromagnets could be used to open up possibilities of enormous expansion in the use of dynamos. By 1870 many inventors had tried their hand at the dynamo and had worked out the primary

BROWN BROTHERS

THOMAS A. EDISON WITH HIS ORIGINAL ELECTRIC LAMP AND A LATER IMPROVED VERSION

variations of winding its coils. But these machines produced variable currents useful only for some electroplating and a few arc-lighting systems. Most electric current in commercial use was still furnished by batteries.

The decisive steps were taken from 1865 to 1870. Pacinotti's improved methods of winding produced a steady current but attracted little notice. Here again the strategically important invention was a critical revision of an existing machine, for Gramme in 1870, utilizing the same principles and a ring armature, produced what was to be a commercially successful source of power.

In 1873 at the Vienna Exhibition occurred one of the great accidental discoveries: it was found that Gramme's dynamo was reversible and could also be used as a motor. There followed a rapid advance of the electrical industry, so that by 1880 the primary accomplishments in lighting, traction, and production of power were realized in practice.

The first important use of electrical power available in greater quantities was for incandescent lighting systems. Warren de la Rue in 1820 and Joseph Wilson Swan in 1878 had tried to replace

the arc lamp with an incandescent electric lamp, with only experimental success. Beginning in the fall of 1877 Thomas Edison made a long series of trials and finally recognized that the solution lay in the broader problem of the general design of a lighting circuit. He then devised the parallel circuit and worked out with great originality all the primary details of mains, house circuits, and connections with the dynamos. This redefined the problem of the lamp itself, for no adequate illumination could be

THE FIRST THERMIONIC ELECTRON TUBES INVENTED BY J. A. FLEMING FOR RECTIFYING HIGH-FREQUENCY OSCILLATIONS

obtained unless the resistance of the lamp was much greater than anything previously tried. By the fall of 1879 Edison turned to carbonized filaments. Problems of detail, especially the evacuation of the glass bulb, were gradually solved, and a successful demonstration was made on Oct. 21, 1879. Electric lighting for the world was born.

Edison's concept was wider than just electric light. His essential achievement was a combination of many electrical devices in a comprehensive system for the production and distribution of electricity. In addition to the electric light and the dynamo, Edison solved problems of wiring, meters, and fixtures, and he even made improvements in the reciprocating steam engine to give more regular and efficient operation at the central power station.

The building and equipment of a central station and its distribution system required a large outlay of capital. Since the demand for electric light was only for six or seven hours a day, even then requiring only about 10% of plant capacity for efficient operation, there was a powerful incentive to encourage wider uses of electricity, both domestic and industrial. Such an extension of electricity required: (1) improvement of prime movers of greater efficiency and capacity, *e.g.*, the steam or water turbine; (2) new techniques of long-distance transmission of electrical power; and (3) further development of flexible and efficient electric motors in sizes and types suited to a wide variety of uses.

The key to the transmission problem lay in use of high-voltage alternating current. Edison had advocated low-voltage direct current for safety reasons, and Marcel Deprez actually tried this method (1880-90), but after 1885 advances in the technical problems of production and transmission of alternating current, plus the special problems of transformer design and the production of suitable alternating-current motors, led to new possibilities.

A power house was begun at Niagara Falls in 1891. By 1907-08 ten turbines of 5,000 hp. each were in operation driving alternating-current generators to supply large quantities of electricity, not only to local plants built especially to use it but also to an area of more than several hundred square miles. Thus a new stage in the production of power had been reached. Power plants of this sort grew rapidly in size and numbers throughout the world. All that remained was to connect them into power networks to make possible wide electrification of areas without other sources of power, as well as to change the entire character of factories using electric motors as their primary source of power.

3. **Electronics.**—The telegraph and the telephone had made

communication quick, cheap, and easy over vast distances, but inventions growing out of two areas of pure science were to change communications even more profoundly. This resulted from discovery of the "Edison effect" in 1883 and the experiments of Heinrich Hertz in 1886. Still later, in 1904, John Ambrose Fleming, with his invention of the first thermionic electron tube, was to take up the properties of electron discharge in a way to make wondrous things possible. Also, the scientific work of Maxwell, Henry, Kelvin, Kirchhoff, Heaviside, and Helmholtz was waiting practical application.

The first man to explore the practical possibilities of electromagnetic waves was Guglielmo Marconi, who in 1899 achieved practical success in transmitting radio (then called "wireless") signals, utilizing high voltage across a spark gap as the transmitter and a coherer as the receiver. From his first limited success with very simple circuits, Marconi applied the concept of tuning, which made possible much greater ranges. The next step was to find a better detector of the radio waves than the coherer, and in 1902 Marconi invented the magnetic detector. This was soon followed by electrolytic and crystal detectors, the latter using materials such as silicon or galena, the ancestors of the modern transistor. By 1901 Marconi had initiated transatlantic radio communications, and by 1910 most ships had regular wireless communication available.

In 1906 Lee De Forest improved the experimental diode of Fleming by adding an intervening grid to the hot filament and plate. This grid made it possible to control the flow of electrons from the filament to the plate. De Forest's triode made possible enormous amplification of the feeble radio currents, both as a detector and as an amplifier. Though De Forest recognized the triode's amplifying properties in a suitable circuit, it remained for Edwin Howard Armstrong to study the characteristic curves of this thermionic valve and to show how it could be used for simultaneous rectification and amplification. In 1913 the feedback circuit, produced simultaneously by several men, was introduced to

THE BETTMANN ARCHIVE

LEE DE FOREST AND HIS TRIODE TUBE, 1906

increase the amplification, and Armstrong's superheterodyne circuit of 1919 provided the capstone.

The age of electronics had dawned and was publicly recognized when radio broadcasting began in the 1920s. Intensified work in applied research, *e.g.*, in improvements in vacuum tubes, made television experimentally possible in 1927 and contributed to a host of other applications, such as the electron microscope, electronic

controls of machinery, and computers, which followed at bewildering speed.

Meanwhile, the principle of the old crystal detector was to come into its own after A. H. Wilson's 1930 exposition on semi-conductors and J. Bardeen, W. Shockley, and W. H. Brattain's first practical transistor of 1948. The transistor (*q.v.*), along with developments in the 1960s in integrated circuitry, created thousands of new uses for electronics, in industry, in the home, and in outer space.

**TECTONOPHYSICS**, a word coined in 1939 by N. L. Bowen, embraces the application of geophysical methods to the study of the physical forces involved in the formation and deformation of the earth's crust. These physical aspects, together with their geological and chemical counterparts, provide a complete description of the structure of the earth's crust and of the changes affecting it. The physical processes chiefly find expression in faulting, folding, and mountain-building episodes (orogenies, diastrophism) by which the crust has been built up. The chief concern of this article is the mechanism of mountain building and its sources of energy. (For crustal movements and deformation, see **FAULT**; **FOLD**; **EARTHQUAKE**. See also **GEOLOGY: Structural Geology**.)

**The Earth's Interior.**—The causes of mountain building lie in the earth's interior. Seismic waves from earthquakes and explosions show this to be divided into three chief layers: a liquid central core, 2,170 mi. (3,492 km.) in radius; a surrounding mantle, 1,800 mi. (2,900 km.) in thickness, of solid, dense rock; and a thin crust. It is in the mantle that the causes of mountain building must be sought.

The crust is about 3 mi. thick under the oceans and 20 to 45 (32 to 72 km.) thick under continents and mountains, the thickness varying with elevation. The oceanic crust is generally thought to consist of basaltic rock beneath a thin layer of sediments; the thicker continental crust consists chiefly of granitic (or gneissic, in a structural sense) rocks and rocks of sedimentary origin. Basalt may extend beneath them to form a continuous layer about the earth.

It is not certain whether any unaltered samples of the mantle reach the surface, and ignorance of its precise nature is the chief cause of uncertainty about tectonophysics. Whereas the mantle was formerly believed to be composed of a more basic silicate than any rock common in the crust, some modern views tend to regard the upper mantle as a high-pressure phase of the rock in the crust.

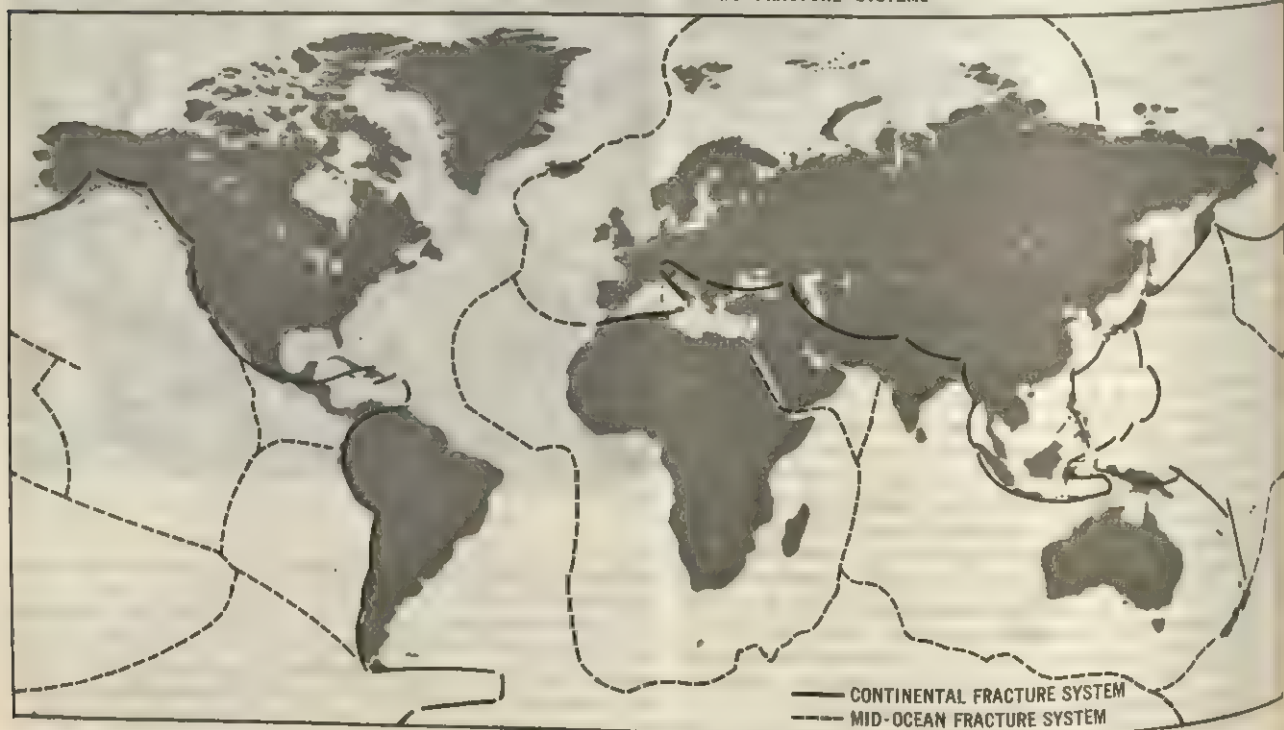

The upper boundary of the mantle is thought to be the Mohorovicic discontinuity, sometimes called the Moho, or M, which occurs at a depth of about 4 mi. (6 km.) under the oceans, while it is at a depth of about 25 mi. (40 km.) under the continents (see **SEISMOLOGY**). The Mohole project to drill through the relatively thin oceanic crust into the mantle was initiated to investigate the differences in composition and nature between the crust and the upper mantle.

The crust and upper mantle are marked by two fracture systems (see fig. 1). The less active is the mid-ocean system, which extends down the centre of the Atlantic Ocean and, passing south of Africa and Australia, crosses the Indian and Pacific oceans. It is a wide, rifted, submarine ridge along which occur shallow earthquakes and occasional volcanic islands of basalt, like the Azores.

The more active continental system consists of those belts of young mountains and island arcs that rim the Pacific Ocean and form the Alpine and Himalayan mountains. Along it lie the highest mountains, the deepest ocean trenches, all deep-focus earthquakes (from 45 to 450 mi. deep), and most volcanoes (see **EARTHQUAKE**; **VOLCANO**).

The lava, steam, and other gases erupted by volcanoes arise from the mantle in such quantities and of such compositions that the whole of the continents, oceans, and atmosphere, respectively, may have grown by their additions during geological time. That this growth did occur is indicated by the zoned structure of continents, with the present, active mountains generally on the margins and successively older mountains and roots of mountains ranged around a few very old continental nuclei. The basaltic

FIG. 1.—CONTINENTAL AND OCEANIC FRACTURE SYSTEMS

FIG. 2.—(A) MECHANISM FOR MOUNTAIN BUILDING; (B) MECHANISM FOR CONTINENTAL DRIFT

lavas erupted by volcanoes in the course of geologic time could have been converted, by erosion and subsequent recrystallization, to the gneissic rocks of the present landscape.

Fundamental to an understanding of tectonophysics is the question of the strength of the earth and whether it fails by flow or by fracture. The answer is not simple nor is there complete agreement on the following hypothesis: The earth's reaction to tides and to earthquakes indicates a rigidity greater than that of steel, but flow is suggested by the precise adjustment of the earth's oblate shape to its speed of rotation and by the slow rise of those lands, like Canada and Scandinavia, that were depressed by the weight of former ice sheets. (See also GEODESY; ISOSTASY.)

The apparent contradiction has been resolved by assuming that the earth is brittle to quick motions but capable of slow plastic flow. When it is realized that all but the outer few miles of the solid mantle of the earth is at a temperature of thousands of degrees and that, if exposed, it would appear white-hot, it is easier to believe that creep at rates of about an inch a year may be taking place within the solid earth.

**Theory.**—An early theory of mountain building was the contraction hypothesis, according to which the earth was formed from the sun and has been cooling ever since. Thermal contraction was considered to have pushed up mountains like wrinkles.

The discovery of radioactive elements in 1896 and the realization that their decay generates heat made it uncertain whether the interior of the earth is cooling or not. Some believe that the amounts of uranium, thorium, and potassium are small and that the earth, at least to a depth of several hundred miles, is cooling. In 1929 Sir Harold Jeffreys enunciated the general physical principles of the contraction hypothesis, and 20 years later A. E. H. Love showed that mountains formed by horizontal compression might be expected to have the arcuate forms and some other features observed in mountains and island arcs, but no explanation depending upon contraction has been offered for mid-ocean ridges.

Others believe that more heat is generated than can be carried off by conduction, and F. A. Vening Meinesz and Arthur Holmes suggested the convection current hypothesis, according to which the earth's mantle is very slowly turning over in gigantic convection cells that bring heat to the surface and raise mountains. If this is so, the currents probably rise beneath the mid-ocean fracture system (see fig. 2) and sink beneath the continental fracture system.

About 1910 F. B. Taylor and A. Wegener pointed out that the similarities in shapes and geology of several adjacent coasts, and especially the Atlantic shores of Africa and South America, suggested that they were formerly united and that the continents have moved apart, pushing up the Andes and the Alps in their advances.

They offered no adequate explanation for this theory of continental drift (see CONTINENT).

Recent measurements of the direction of magnetization prevailing when certain old rocks were formed have supported the idea of polar wandering—that the poles and axis of rotation have moved relative to the crust. According to some interpretations, there is evidence of independent movements of the continents also. (See GEOMAGNETISM.)

In 1937 P. A. M. Dirac stated that there is no proof that the attraction due to gravity has remained constant and proposed that its slow weakening causes the observed expansion of the universe. S. W. Carey and B. C. Heezen have tried to explain tectonophysics by a theory of an expanding earth.

Finally various suggestions have been advanced to explain the earth's surface features as a result of the birth of the moon from the Pacific Ocean or of the impact of large meteorites, but these theories are hard to reconcile with geological evidence.

Limited knowledge prevents a final decision, but information gained since 1946, when the extensive exploration of the ocean floors began, suggests that a compromise solution may be possible. J. D. Bernal, R. S. Dietz, and H. H. Hess hold that convection cells move in the mantle at the rate of about an inch a year. These currents rise and separate under the mid-ocean ridges, uplifting them, producing the observed rifts, and providing the measured high flows of heat. Such currents rising under the mid-Atlantic ridge could have formed the South Atlantic Ocean and separated Africa and South America during the past 200,000,000 years in accordance with geological evidence. These currents are considered to sink along the continental fracture system, producing its compressional features.

According to this view, the blocks of continental material do not drift through the mantle but are borne along in random motion on its currents, sometimes splitting and moving apart, as across the Atlantic, and sometimes amalgamating to form composite continents like Asia. The margins of the continents also grow by the accumulation of lavas and sediments. Thus, the gneisses of the continents are considered to be rafts of material exuded from the interior, accumulated, and altered, but the basaltic crust is only a low-pressure phase of the top of the mantle. The distribution of former mountain systems can be explained by migration of convection cell currents from time to time.

This theory of tectonophysics thus combines part of several older theories, including convection, drift, growth, and compression. Even slow expansion of the earth is not entirely excluded and may indeed be necessary to provide space in the ocean basins for the ascension of volcanic waters that would otherwise have drowned the continental platforms. (See also EARTHQUAKE: Theory and Research.)

**Other Forces.**—Most geophysicists would agree that the forces that build mountains are primarily thermal. This is true both for the concept of a cooling and shrinking earth, and for the more widely held view that radioactive elements heat the earth and give rise to its internal motions. Besides these major forces that build mountains, there are others that change the level of the surface by gentle warping.

Chief among these are the force of gravity and the transport of material about the earth's surface through the indirect agency of the sun's heat. Important loads are moved in the form of snow. During the past 1,000,000 years about 6,000,000 cu.mi. of ice have been accumulated and maintained in the form of ice sheets on Greenland and Antarctica. The force of gravity acting on these loads has depressed the land beneath them by several hundred feet. Other lands around the Polar Basin, such as Canada and Scandinavia, from which similar ice sheets were removed by melting about 11,000 years ago, are still rising at rates up to three feet a century as a result of readjustment by slow flow or creep within the mantle.

The sun's heat also transports water, which in rivers carries sediment to the margins of continents to accumulate in great deltas and shelves. These also settle, and this is believed to be the reason why most of the Atlantic coast of North America is sinking relative to sea level at a rate of 1-2 ft. per century. Holland, at the mouth of the Rhine, is sinking even faster, and places from which the sediment is derived rise. A minor cause of disturbances that has recently been recognized is the impact of large meteorites. The largest crater recognized definitely to be so formed is the Vredfort Ring in South America, which is a semi-circular ring of hills with a diameter of 30 mi.

**TECUMSEH** (TECUMTHE) (c. 1768-1813), a Shawnee who attempted to create a pan-Indian alliance to revitalize tribal culture and preserve tribal lands. Born in present-day Ohio, he was acquainted from boyhood with border warfare. As an adolescent he participated in the campaigns of the Shawnee and their neighbours against the Kentuckians who were beginning to cross the Ohio River. His father and two elder brothers were killed in the struggle against white encroachment, which culminated in the defeat of the Indians at Fallen Timbers (1794). At the ensuing Treaty of Greenville (1795) the Indians made a substantial cession of land north of the Ohio. Refusing to attend the treaty council, Tecumseh broke with the reigning Shawnee chiefs and gathered a following of dissident warriors. Never recognized as a chief by an official council, Tecumseh was called by his followers "Chief of the Beautiful River."

Tecumseh found his principal white opponent in Gov. William Henry Harrison (q.v.) of the Indiana Territory. Between 1802 and 1809, Harrison secured the cession of 33,000,000 ac. of Indian land north of the Ohio. Tecumseh angrily ascribed the loss to the corruption of the "peace" chiefs who had signed the treaties. He found an ally in his brother Laulewasikau (or Tenskwatawa), known as "the Prophet," who in 1805 temporarily assumed leadership of the revitalization movement. Armed with his declaration that he had been taken up to the spirit world and was now bearing a revelation from the "Master of Life," the Prophet announced that the Indians could recover their lands and their integrity by abstaining from alcohol and the other perversions of white civili-

zation, deposing the peace chiefs, ceasing intertribal warfare, and uniting against the white invader. Tecumseh traveled from the Scioto River to the Arkansas and from the Great Lakes to the Gulf of Mexico to preach the necessity of a pan-Indian alliance. In addition to his personal renown as an orator, warrior, and dancer, he exploited the Prophet's appeal to Indian faith in the supernatural. Tecumseh was most successful with the Shawnees' fellow Algonkian-speaking tribes, and also with the Wyandots and with the Creeks (his mother's tribe). His appeal was especially effective with factions of young warriors rebelling against the domination of the peace chiefs.

During the time when he was consolidating the intertribal alliance, Tecumseh also held councils with Harrison, insisting that the governor's treaties were illegitimate because they were not signed by all the tribes north of the Ohio. He maintained that no particular tribe could cede land, because the hunting grounds belonged to all tribes in common. Probably he misrepresented Indian custom with respect to land tenure, but his views reflect the experience of the Shawnees, who had long lived as "guests" in the hunting territories of other tribes.

In November 1811, while Tecumseh journeyed among the southeastern tribes, the Prophet's warriors attacked an expeditionary force under Harrison and were defeated at the Battle of Tippecanoe. Discredited, the Prophet fled to British Canada.

The Shawnees had fought on the British side during the American Revolution, and Tecumseh long hoped for British aid against the Americans. The British, however, refused him official encouragement until the outbreak of war between the United States and Britain in June 1812. At that point, Tecumseh and his followers allied with the British forces at Ft. Malden. They fought several successful campaigns along the Canadian border, but U.S. Capt. Oliver Hazard Perry's naval victory at Put-In-Bay cut their supply lines and forced them to withdraw. During the retreat across Ontario from Ft. Malden, Tecumseh persuaded the British commander to make a stand at the Thames River. In the Battle of the Thames, Tecumseh was killed (1813). With him perished the project of a pan-Indian alliance.

**TEDDER, ARTHUR WILLIAM TEDDER**, 1ST BARON (1890- ), British air marshal, who had a large share in the success of the Allied landings in Normandy in World War II, was born at Glenguin, Scot., in 1890 and educated at Whitgift School and Magdalene College, Cambridge. He was commissioned in the army in 1913 and served in France in World War I, being attached to the Royal Flying Corps in 1916. He was granted a permanent commission in the Royal Air Force in 1919.

In 1934, after service in a number of training establishments, he was appointed director of training. From 1936 to 1938 he was air officer commanding the Far East Command. He then returned to the Air Ministry as director of research and development. Early in World War II he became deputy air member for development and production at the Ministry of Supply. In 1941 he was appointed air officer commanding in chief in the middle east, and subsequently he took command of all the Allied air forces in that area. During his command the air force played a notable part in expelling the enemy from North Africa. In 1944 he was deputy commander of the Allied Expeditionary Force under Gen. Dwight D. Eisenhower and played a large part in planning and controlling the Allied landings in Europe. Much of his success was due to the efficient manner in which he cooperated with other Allied forces. Between 1946 and 1950 Lord Tedder was the first peacetime chief of the air staff and senior member of the air council. He was created knight grand cross of the Order of the Bath in 1942 and elevated to the peerage in 1946. (E. B. Bn.)

**TEDDINGTON**, a part of Twickenham in the borough of Richmond upon Thames (q.v.), London, Eng., mainly residential, lies on the river close to Bushy Park and Hampton Court Palace. Teddington Lock is the biggest on the Thames. The National Physical Laboratory, the National Chemical Laboratory, and the

BY COURTESY OF THE CHICAGO NATURAL HISTORY MUSEUM

19TH-CENTURY PORTRAIT BELIEVED TO BE OF TECUMSEH

Teddington Laboratory are scientific establishments in the locality. Eminent residents have included Peg Woffington, the actress, who died there in 1760 (see *WOFFINGTON, PEG*); Robert Dudley, earl of Leicester; William Penn, the Quaker; Richard Doddridge Blackmore, the author of *Lorna Doone*, who also died there; and Noel Coward, the playwright and actor, who was born there. (W. H. Jo.)

**TEES**, a river of England that rises on the east side of Cross Fell in the northern Pennines and flows 70 mi. (113 km.) SE and E to the North Sea, draining an area of more than 700 sq.mi. (1,800 sq.km.).

Its upper course forms the boundary between the counties of Durham and Westmorland. From its source to below Middleton it flows in a typical Pennine dale through an attenuated ribbonlike strip of farmland flanked by high, bleak, and peaty tracts of moorland. At Caldron Snout and again at High Force there are attractive waterfalls where the river crosses the hard dolerite outcrop of the Whin Sill. From Caldron Snout, right to its mouth, the river forms the boundary between the counties of Durham and Yorkshire. Below Middleton the valley opens, and its farmlands become more extensive. The river flows past Egglestone Abbey, Rokeby Hall, and Barnard Castle—well known through Sir Walter Scott's poems—and receives important right-bank tributaries, the Lune, Balder, and Greta, from subsidiary dales to the west. The last-named carries an important route, crossing the Pennines by the saddle of Stainmore. Below Barnard Castle the Tees meanders across a fertile clay plain to its estuary below Middlesbrough, where, until the 19th century, it entered the sea by shifting channels among extensive mud flats. The tortuous channel below Stockton-on-Tees has been straightened by artificial cuts, and, since 1854, the channel through the estuary has been concentrated and trained by the Tees Conservancy Commission. Extensive areas along the estuary shores have been reclaimed by dumping slag.

The river is tidal to Worsall, but the historic crossings carrying the main south-north lines of communication lie upstream—in Roman times at Piercebridge and later near Darlington. In its lower course the chief tributaries are the Skerne, entering by Darlington from south Durham, and the Leven from the Cleveland Hills, entering below Yarm. An old river port, Yarm lost trade to Stockton-on-Tees, and the latter in turn to Middlesbrough, when the railway was extended there in 1830; but most of the trade is now handled directly for the great chemical and iron and steel works of the estuary shores at their own jetties, and, since 1950, Teesport has been developed as an oil terminal. Until the 20th century Stockton-on-Tees was the lowest bridge point, but there are now bridges at Middlesbrough. Middlesbrough and Stockton-on-Tees (*qq.v.*) are the main centres of a great industrial conurbation that has developed since 1825 along the Tees between the Durham coalfield and the Cleveland ironstone field. The estuary area itself is underlain by important deposits of salt and anhydrite that are among the bases of its chemical industry.

(AR. E. S.)

**TEETH** are hard white structures found in the mouth in man and many animals and used variously for mastication of food, seizing and holding objects, combat, cutting, chiseling, and other incidental purposes. Each tooth consists of a crown and one or more roots. The crown is the functional part that is visible above the gum. The root is the unseen portion that supports and fastens the tooth in the jawbone. The shapes of the crowns and the root characteristics vary in the different parts of the mouth and from one animal to another.

The different modern dentitions have been attained under the pressures of biological laws of evolution (see *Evolution and Comparative Anatomy*, below). Some dentitions are very restrictive and adapted to a particular diet. Carnivores cannot chew the fresh grass or hay that makes up the diet of a horse, nor can sheep handle a meat diet. Other dentitions, like that of man and the great apes, are very general (omnivorous) and can prepare both flesh and vegetable foods. Modern man's dentition is highly variable and shows signs of general reduction in size and form, as compared with the dentition of fossil man.

Occasionally the statement is made that man gradually is losing all his teeth. This is based on the observation that certain teeth fail to develop in some individuals and are of a reduced form in others. To conclude that the trend must continue is a fallacy. The future survival and selection pressures of evolutionary laws will determine the fate of man's dentition, not the fact that the present shift is in a given direction.

**Human Dental Anatomy.**—Man has two sets of teeth during his lifetime. The first set is acquired gradually between the ages of six months and two years. As the jaws grow and expand, these teeth are replaced one by one by the teeth of the second set. The first set is known as the milk, deciduous, or primary dentition. The second set is called the permanent, or secondary, dentition. The permanent molar teeth are not replacements but additions and increase the capacity of the dentition as the jaws increase in size.

The right side of a dentition is, except for minor variations, a mirror image of the left. The upper teeth differ from the lower and are complementary to them; the relationship is in some respects similar to that of a mortar and pestle. There are 5 deciduous teeth and 8 permanent teeth in each quarter of the mouth, making a total of 32 permanent teeth to succeed the 20 deciduous ones. Each quadrant has four specific types of teeth, which have different shapes and uses. These are the incisors, the canines (or cuspids), the bicuspid (or premolars), and the molars (see fig. 1).

FIG. 1.—SKULL OF A FOUR-YEAR-OLD CHILD, SECTIONED TO SHOW ROOTS OF THE DECIDUOUS TEETH AND TOOTH GERMS OF THE PERMANENT TEETH

**Incisors.**—The permanent incisors, of which there are two in each quarter of the mouth (total number eight), are used principally for biting and cutting. The upper ones have a delicate tactile sense that enables them to be used for identifying objects in the mouth by nibbling. The biting portion is wide and thin, making a chisel-shaped cutting edge. The upper central incisor is the largest. The lateral incisor, next in line, is smaller and sometimes irregular in form. The lower ones are much smaller and are very similar to each other. They bite against the upper incisors, either edge to edge or slightly inward on the tongue side. An edge-to-edge biting position is acquired as the teeth wear down, particularly among peoples whose main foods are coarse or gritty.

**Cuspids.**—Next to the incisors is the canine, or cuspid (total number four). It is at the corner of the mouth, the third tooth from the midline. It frequently is pointed and rather peglike in shape. The cuspid is absent in many mammals that have developed protective horns; in some other animals it is a great defensive weapon by virtue of its size. In man the cuspid tooth has the function of cutting and tearing. Its length and position are such that it does not normally protrude beyond the level of the other teeth, and this permits a side-to-side chewing motion that is not possible in the other primates, which have long canines. The upper cuspid in man is popularly called the eyetooth, from its position under the eye.

**Bicuspid.**—The two bicuspid, or premolars (total number eight), are next in line. They replace the baby molars but have a somewhat different function. Each has two cusps (tapering pro-

jections on the crown), although the lower second bicuspid frequently has a small third one. The first lower bicuspid often has a compressed appearance, as though it had been squeezed on the sides. This gives a prominence or sharpness to the forward sloping edge that is reminiscent of the scissors action against the long upper cuspid of man's remote ancestors. The roots of the bicuspids are reduced forms compared with those of fossil and modern anthropoids. The upper first bicuspid generally has two roots, sometimes one; the second generally has one root, sometimes two; the lower bicuspids have one root each. Occasionally they are found divided in two.

**Molars.**—The three molars (in each quadrant; total number 12) are the teeth farthest back in the mouth. They are used exclusively for grinding. The upper molars have four (sometimes three) cusps, whereas the lowers have five (sometimes four). The number and position of the cusps and the character of the grooves between them differ among individuals. Generally the upper molars have three roots and the lowers two.

In persons of European origin the first molar usually is large, the second smaller, and the third the smallest. In some other groups the third molar is larger than the second, though smaller than the first.

**Deciduous and Permanent.**—In the milk, or deciduous, dentition there are only 20 teeth, 10 in each jaw, 5 in each right and left segment. They include, in each quadrant, 2 incisors, 1 cuspid and 2 molars. The molars are replaced by the permanent premolars, or bicuspids. The incisors and cuspids are replaced by the permanent incisors and cuspids. In the deciduous dentition there are no predecessors to the three permanent molars. The deciduous dentition differs from the permanent in its smaller size, whiter colour, greater constriction of the necks of the teeth, and in the fact that the roots of the molars are widely spread to give a wider base and an accommodation for the developing permanent tooth germs.

**Eruption.**—This term refers to the emergence of teeth through the gums in living persons; in the study of fossil or recent skeletal remains it means emergence above the level of the jawbone. Eruption is variable among individuals both as to timing and as to order. In the deciduous dentition the lower first, or central, incisor comes in first, between the sixth and ninth month. This is followed by the upper central and lateral incisors. The other teeth erupt at four- to six-month intervals, the dentition being completed by two years of age. The sequence of permanent-tooth emergence follows different patterns in different individuals. In some, the lower first molar is the first permanent tooth to appear; in others it is the lower central incisor. This occurs about the sixth year.

From this time on there is a succession of loss of deciduous teeth and emergence of permanent teeth in the presence of jawbone growth, expansion, and change. This process continues intermittently with rest periods until about age 12, when the second molars arrive. The third molars, or wisdom teeth, usually do not come in until about age 18 or 20. Occasionally a deciduous tooth is retained into adulthood when its successional tooth fails to develop or when the permanent tooth is in an abnormal position. This follows a genetic pattern, along with other phenomena of the dentition.

**Histology.**—Teeth are composed of several tissues (fig. 2).

**Dentin.**—The main bulk or core of each tooth is dentin, a calcified tissue made up of approximately 30% organic matter and water and 70% inorganic matter, principally calcium and phosphorus. Dentin is a highly sensitive tissue with a circulation of lymph in its tubules. The tubules extend from the inner pulp cavity to the periphery, more or less perpendicularly to these surfaces. The dentin extends almost the entire length of the tooth, being covered by enamel on the crown portion and by cementum on the roots.

**Enamel.**—Enamel is the hardest tissue in the body, consisting of 96% inorganic material and 4% organic matter and water. This tissue receives its nourishment, slight as it is, from the dentin that it covers. Some circulation of fluids in enamel has been shown by use of radioisotope tracer materials. The enamel has

no nerve supply. Microscopically, it is seen to be composed of fine, hexagonal prisms arranged at right angles to the outer surface of the tooth and extending to the underlying dentin.

**Cementum.**—Cementum is another calcified tissue. It affords a thin covering to the root of the tooth and has the appearance of a modified type of bone. In a few instances, as in horses and rabbits where the enamel is folded, the cementum extends beyond the confines of the root surface and fills these folds, thus serving as a substantial part of the functional chewing surface. It serves normally as a medium for attachment of the fibres that hold the tooth to the surrounding tissues (periodontal membrane).

**Pulp.**—Nerves, lymph, blood vessels, and fibrous tissue make up a structure generally known as the pulp or "nerve," occupying a cavity located in the centre of the tooth. The pulp canal is long and narrow with an enlargement, the pulp chamber, in the coronal end. The canal extends for about four-fifths the length of the tooth, with communication to the general nutritional and nervous systems through the apical foramina (holes) at the end of the roots. Lining the entire wall of the pulp cavity are the resting odontoblasts (columnar connective-tissue cells) that originally functioned to produce the tubules of the dentin. Upon stimulation from decay or other external contact to the dentin proper, the odontoblasts may again resume activity and produce another layer of so-called secondary dentin. This differs somewhat from the first dentin; it is less well organized and in certain respects

BY COURTESY OF AMERICAN DENTAL ASSOCIATION

FIG. 2.—CROSS-SECTION OF A HUMAN MOLAR

resembles bone. Secondary dentin is a protective mechanism, designed to counter the losses from the advancing carious (decay) or wear processes.

**Embryology.**—Teeth are produced by specialized tissues induced and organized from simple elements of the ectodermic and mesodermic layers of the embryo. During the seventh to tenth week of fetal life, ten distinct and separate thickenings of certain cell groups develop in the epithelial covering of each jaw. Each of these so-called enamel organs stimulates some of the underlying mesodermic cell elements to transform their character for the specialized function of producing a protoplasmic substance in the form of tubules, which later calcify and form the dentin.

At the same time the cells of the thickened epithelial layer also differentiate into enamel rod producers. The sum total is a tooth

germ in which the process of enamel and dentin production goes on simultaneously from a common starting lineup of cells, the enamel cells (ameloblasts) proceeding outward and the dentin cells (odontoblasts) inward (fig. 3). Thus, the enamel and dentin

FROM BALINT J. ORBAN, "ORAL HISTOLOGY AND EMBRYOLOGY," 4TH ED. (1957), THE C. V. MOSBY COMPANY

FIG. 3.—DIAGRAMMATIC ILLUSTRATION OF THE LIFE CYCLE OF THE TOOTH (A) Initiation (bud stage); (B) proliferation (cap stage); (C) histodifferentiation (bell stage) and active morphodifferentiation; (D) apposition; (E) intraosseous; (F) eruption into oral cavity; (G,H) attrition

are developed in direct contact with each other. The tissues soon are calcified by deposition of calcium salts in the matrices of processes and tubules. The ameloblasts remain on the surface after enamel formation is completed. After eruption of the tooth they frequently are a source of annoyance by their affinity for stains and surface discoloration. At the termination of dentin production, the odontoblasts remain as a lining of the pulp chamber, ready to resume function by formation of the secondary dentin upon the proper stimuli (see *Pulp*, above).

**Evolution and Comparative Anatomy.**—Teeth and bone have figured conspicuously in evolutionary studies and theory; they constitute major evidence in prehistoric studies. The teeth, particularly, persist through time by virtue of their calcified structure and their resistance to erosion and the various conditions of burial. With a few exceptions, the history of the evolution of tooth form and structure is complete. Comparison of the many modern dentitions with their predecessors reveals their origins and transition. Modern man's dentition differs from that of his fossil forebears in the size of teeth and in the proportionate development or modification of structural parts. Similar points of difference are found between man and the other anthropoids. The differences between tooth forms and combinations in the animal classifications are striking.

Various theories have been proposed to explain the evolution in form from the simple conelike tooth of the early reptiles to the complicated patterns of human molars. In early discussions of the subject disputes over some sequences and stages were common. The fossil record, however, now indicates clearly the pathway of these changes. The theory of tritubercle, developed largely by the U.S. paleontologists E. D. Cope and H. F. Osborn, has had the greatest influence. According to this theory, the simple peglike tooth, originally derived from the placoid scales, developed two additional smaller pegs or cones, one in front of (paracone) and one behind (metacone) the original main cone (protocone). This is known as the triconodont stage and is represented by fossils of extinct mammals. The two added structures were supposed then to have moved externally in the upper teeth and internally in the lower, to form a triangle. Specimens are known that show that these cusps evolved in this triangular position and did not migrate. This tritubercled tooth is considered the basic ancestral form from which all modern mammalian dentitions were derived, by addition

and subtraction as well as by modification of cusps. The names of the cusps as developed in the Cope-Osborn system still are used in the literature, although later evidence shows a few discrepancies in the plan. As an example, the internal anterior cusp of modern upper primate molars bears the name protocone, indicating that it is homologous with the original reptilian single-coned tooth. It is in reality a later added cusp; the paracone (outer anterior cusp) is the true representative of the first cusp. Nevertheless, the organization of thinking and the impetus given this field of study by Cope and Osborn were extremely significant.

The first teeth were not teeth as they are now known. They were not calcified, nor were they firmly attached to the underlying supporting structures and tissues; neither were they confined to the jaws. Even today this is true of some lower forms of animals.

Fish display the earliest trends in the evolution of teeth. In some, the scales at the edge of the mouth are used as teeth and are replaced by the ones next in line as they are needed. Some fish have calcified structures as in the higher animal forms, generally confined, however, to a single cone shape. These are constantly formed in the jaw and erupt from time to time to succeed their predecessors as they are worn out or lost.

FIG. 5.—NINE STRUCTURAL STAGES IN THE EVOLUTION OF TEETH FROM THE SIMPLE HOMODONT STATE (A) TO THE COMPLEX HOMINOID HETERODONT STAGE (I)

Key: PA = paracone; P = premolar; M = molar; C = canine or cuspid; PR = protocone; HY = hypocone; HYL = hypoconulid; ME = metacone; EN = entocone

A brief description of the teeth of the members of the main vertebrate groups follows.

**Cyclostomes.**—In the lampreys and hags the teeth are horny cones.

**Elasmobranchs.**—These include the cartilaginous fishes, such as sharks and rays, in which the teeth are arranged in several rows. The hind ones move forward as those in the front row fall out. In some of these fishes the teeth are set in positions like flat pavement blocks; in the rays they are like flat plates that crush against each other. This flatness gives them the appearance of the molars of man. Except for the saw of the sawfish, elasmobranch teeth are not embedded in sockets. The body of the tooth, called the osteodentin, resembles bone and has no pulp cavity; it is therefore unlike the dentin of the higher vertebrates.

**Bony Fishes.**—Both primitive and advanced bony fishes show

FIG. 4.—THREE MAJOR STAGES IN THE EVOLUTION OF TEETH

(A) Homodont stage in which all the teeth have the same form; (B) pre- and post-canine stage in which the dentition has been divided into anterior and posterior parts by the elongation of the canines; (C) heterodont stage in which the teeth have taken on specialized forms and functions, differing in the various locations of the dental arcade

great variability in teeth. In the sturgeon there are no teeth at all, while in other fishes each of the several bones bounding the mouth, including the branchial arches, bears teeth. The pike's mouth and pharynx are completely armoured with teeth. The pike and hake have hinged teeth that bend to allow food and prey to pass down the throat, but become erect and bar exit of anything that has gone by. The hinge is a soft-tissue attachment with elastic ligaments. Most of the bony fishes have osteodentin, but the hake and a few others have vasodentin, which has many blood vessels running through it.

**Amphibians.**—These include the frog, toad, and salamander, among others. Although the teeth are less numerous than in the first three classes, they do occur regularly on the palate as well as on bones and make up the lower and upper jaws proper. The toad has no teeth, and the frog has none in the lower jaw. The extinct stegocephalid amphibians, ancestral to the reptiles, are of particular interest because of their complex convoluted type of dentition, known as labyrinthian. They are called labyrinthodonts.

**Reptiles.**—These have considerable variety in the dentition. The first separation of anterior from posterior teeth by the specialized elongation of the canine tooth occurred in this class.

Turtles have no teeth, although the ectodermal ingrowth (dental band) from which teeth develop in other animals is present in the turtle embryo. The place of the teeth in these reptiles is taken by horny jaw cases.

Among the snakes the nonpoisonous varieties have two rows of teeth in the upper jaw, one on the maxilla and another on the palatine and pterygoid bones, while in the lower jaw there is only one row. These teeth are sharp pegs ankylosed to the bones and so strongly recurved that no prey that has passed the teeth can escape. The poisonous snakes have special modified teeth, the commonly known poison fangs in the maxilla of each side; the fang has a deep groove or canal running down it that conducts the poison from the poison gland. In the colubrine snakes, such as the cobra, the poison fang is always erect, but in the viperine snakes, such as the adder and rattlesnake, there is a mechanism by which the specialized tooth is erected only when the jaws are opened for striking. At other times the poison fang lies flat in the roof of the mouth.

In the lizards the teeth usually consist of a series of pegs in the upper and lower jaw, each resembling the one in front of it. In some lizards, as the chameleon, the teeth are ankylosed by their bases to the bone; in others, as the iguana, they are fused by their sides to a wall-like ridge on the lateral surface of the bone. In the former case the dentition is called acrodont, in the latter pleurodont.

Alligator and crocodile teeth are fitted into definite sockets as in mammals and are not ankylosed with the jaws. This arrangement is called thecodont. In this group the 1st, 4th, and 11th teeth of the lower jaw are larger than any of the others. In the upper jaw, the 3rd and 9th teeth from the midline on each side are enlarged. This regularity suggests the pattern of division of the dentition into the various tooth groups that are seen in the mammals generally.

**Birds.**—The modern birds are distinctive in having no teeth, though the fossil record shows that at one time they did. The three known toothed forms are: (1) *Archaeopteryx*, about the size of the modern pigeon, had sharp pointed teeth arising from the margins of the long, slender jaws. These teeth were distributed in a single row and resembled very closely the teeth of certain modern reptiles. (2) *Ichthyornis* had about 20 sharp pointed teeth arranged much like those of the preceding. The tips of the teeth of this bird were slightly curved. They were implanted in sockets and had wide-open roots and a heavy cone of dentin covered with a cap of enamel. (3) *Hesperornis* had teeth that were not set in sockets but were placed in a groove with small bony partitions between the individual roots. The fossil birds all had teeth composed of osteodentin capped with enamel.

In these first six groups of vertebrates the dentitions are quite simple in form, being in the main of the cone type, except for particular specializations. Also in most of these classes there is a continuous succession of teeth, so that replacements for lost teeth

are always at hand. This arrangement for continual succession of teeth is called polyphyodont.

**Mammals.**—Among the mammals may be found a very wide variety of dentitions and specializations. This class has the heterodont type (many shaped) as opposed to the homodont (single shaped) dentition that is found among the other classes. In the mammals the polyphyodont dentition, or continuous succession of teeth, is reduced to a diphyodont dentition; i.e., there is only one replacement of the first set. In the marsupials the reduction is carried still further, for only one premolar in each segment of the jaw is replaced, while in the toothed whales there is no succession at all. When one set has to do duty throughout life the dentition is called monophyodont.

Some of the specializations among the mammals are extreme. The rodents, for example, have incisors that continuously grow throughout life. The horses and other hoofed animals have large teeth that are folded and have very long roots. These long, heavily ridged teeth are practically as efficient as the continuously growing variety. Cats, dogs, and other carnivores likewise have teeth that evolved from the tritubercled form as well as the other orders; however, the dentition of these animals developed in a direction that would serve in cutting, grasping, and shearing rather than grinding. Some mammals lost parts of their dentition rather than added to them. Some, though only a few, of the so-called edentates have lost all their teeth, but even the toothless members have vestiges of teeth in the early developmental stages.

All the primates have similar dentitions. The main differences between them are in the emphasis of expression of parts, in the relative sizes of parts, in the overall size of the dentition, and in the actual number of the types of teeth. The lemurs exhibit a certain coarseness on the surface of the teeth, in contrast with human teeth. They also tend to vary in the number of premolars, from two to four in each of the four quadrants. The aye-aye has even lost all the canines; it retains only the upper and lower central incisor, one upper premolar, and none of its lower premolars. The anthropoids (monkeys, apes, and man) follow a rather consistent formula as to number of teeth; the main exception is that the platyrrhine (New World) monkeys have three premolars in each quadrant, whereas the catarrhine (Old World) forms have two. Some platyrrhines have two rather than the usual three molars.

**Variations in Man.**—Although following a basic pattern throughout, modern man's dentition does show considerable variation from one population to another. The main differentiating characteristics are those in the tongue side of the upper incisor teeth (absence or presence of shovel shape), in the expression of the areas near the gum margin of the posterior teeth (ridges, cusps, and grooves), in the general wrinkling or smoothness of the occluding surfaces, and in the overall size of the dentition.

Failure of certain teeth to erupt has been reported among populations. Absence of one or more third molars, or wisdom teeth, has been reported in 19% of the white populations of central Europe; absence of upper lateral incisors is reported in from 2 to 3% in most groups. Reductions in the form or pattern of certain teeth and modification or absence of certain cusps are also frequently noted. These variations follow a regular pattern, with the third molars, lateral incisors, and second premolars being the teeth most commonly affected. Differences in the frequencies of these occurrences have been used in anthropological studies to describe the dentition of various population groups. One population may be distinguished from another by comparing the different frequencies of these features. The frequencies reflect the characteristics of the genetic composition of populations.

**Dental Formulas.**—It is convenient to indicate the number of each kind of tooth in one side of the upper and lower jaw in the various mammalian orders by the use of dental formulas. The order and number are indicated from left to right, as in the case of

man's formula: incisors  $\frac{2}{2}$ , cuspids  $\frac{1}{1}$ , premolars  $\frac{2}{2}$ , molars  $\frac{3}{3}$ . This

is condensed into  $\frac{2.1.2.3}{2.1.2.3}$ . Some typical formulas are:

Primitive mammalian .....	3.1.4.3
Typical marsupial .....	3.1.4.3
Anthropoidea:	5.1.3.4
Platyrrhina .....	4.1.3.4
Catarrhina .....	2.1. (2-3) . (2-3)
	2.1. (2-3) . (2-3)
	2.1.2.3
	2.1.2.3

For additional information on dentitions (fossil and modern), see articles on particular animal groups. See also references under "Teeth" in the Index.

**TEETH, ARTIFICIAL.** The replacement of missing natural teeth with substitutes of various kinds has been practised from ancient times, when human and animal teeth and wood were used. In the last quarter of the 18th century one-piece restorations of porcelain began to be used, and at the beginning of the 19th century Giuseppangelo Fonzi, an Italian dentist practising in Paris, introduced individual porcelain teeth mounted on gold or platinum bases. Porcelain teeth were introduced into the United States about 1817, reputedly by Anthony A. Plantou. Early in the 19th century, through the efforts of J. Leon Williams, the appearance of artificial teeth was much improved by designing the teeth to harmonize with the shape of the face. Teeth were made in three typical facial forms: square, tapering, and ovoid. At the same time the effectiveness of the chewing surfaces of the back teeth was improved by the anatomical designs of Alfred Gysi of Switzerland.

In modern times porcelain and plastic teeth are made in such a great variety of shapes, sizes, and colours that almost any natural teeth can be closely matched. Modern artificial teeth are usually fastened to plastic bases that resemble the natural gums. The combination of teeth and base is an artificial denture, commonly called a set of false teeth or a dental plate. Artificial teeth are also used in dental bridges, which are cemented to natural teeth.

Dental porcelain is prepared by fusing a mixture of feldspar (orthoclase), flint (silica), and clay (kaolin) at about 2,400° F (1,300° C). The high-melting flint and clay are fused together in a vitreous mass formed by the relatively low-melting feldspar. Much of the fusion is done under a partial vacuum to reduce porosity and increase strength. Suitable opacities and colours are obtained by adding small amounts of metallic oxides, such as those of titanium, chromium, nickel, cobalt, iron, and uranium. The uranium oxide causes artificial teeth to glow (fluoresce) in ultraviolet light in much the same manner as natural teeth.

The manufacture of porcelain teeth begins with the carving of the desired shapes and sizes out of plaster of paris or other suitable material. These models are made one-fifth larger than the finished product to allow for shrinkage during fusion. In one common process, split metal molds are made from the models. Starch, powdered porcelain of varied composition, and water are mixed to a thick paste and packed into the molds. The packing is done in stages: the porcelain mixture (resembling in composition the translucent enamel covering of natural teeth) is packed into the appropriate position in the mold, and a more opaque porcelain (resembling the dentin core of natural teeth) is placed in another part of the mold. The molds are closed and heated to bake the porcelain to a hard state so that the teeth can be removed for a final fusing. Other methods employ flexible rubber molds into which the porcelain paste is vibrated until it is condensed sufficiently to be removed from the mold for final fusing. Bridge teeth are frequently made by fusing a dental porcelain to a precious-metal casting or by veneering the casting with a plastic.

Approximately 30% of all modern artificial teeth are made of plastics, consisting principally of polymethyl methacrylate. By comparison with porcelain teeth, plastic teeth are less brittle, are easier to grind and polish, make a firmer union with the plastic base, and make less noise when being used. However, porcelain teeth are generally preferred because of their chewing efficiency and longer wear.

Artificial teeth are shipped from the factory inserted in wax on plastic cards or blocks. A card usually contains a set of six front teeth (two cuspids and four incisors of either the upper or lower jaw) or a set of eight back teeth (four bicuspid and four molars of either jaw). However, the dentist or dental laboratory may purchase teeth singly or in any combination desired. The normal number of natural teeth is 32, but the four third molars (wisdom teeth) are not supplied in artificial sets because there is usually not room for them in an artificial denture.

**TEFILLIN:** see PHYLACTERY.

**TEGEA**, an ancient Greek city of eastern Arcadia, 4 mi. SE of the modern town of Tripolis, on a plateau enclosed by Mts. Parthenium and Maenalus, east and west, respectively, and by transverse ranges that separate it from the plateau of Orchomenos and from the valley of the Eurotas (Evrotas) River. The southern part of this plain was Tegean territory; the north belonged to Mantinea (q.v.). Tegea's geographical position accounts for its repeated conflicts with Mantinea and with Sparta.

The traditional founder of Tegea was Aleus. The legend that Echemus, king of Tegea, halted the first invasion of the Heraclidae (see DORIANS) by killing Hyllus, son of Heracles, in a duel at the Isthmus of Corinth may reflect a genuine importance of Tegea in Mycenaean times (not proved by archaeology). At an unknown date, nine separate communities were united to form one city. For several centuries Tegea screened Arcadia against expanding Sparta; ultimately subdued about 550 B.C., it was allowed to retain its independence as a Spartan ally. When the Persians invaded Greece in 480, Tegea sent 500 men to defend Thermopylae, and 1,500 Tegeans took part in the Battle of Plataea (479); they were the first to enter the Persian camp. A few years later the Tegeans headed a coalition of Arcadians and Argives against Sparta, but after losing two battles at Tegea and Dipaea (dates uncertain) they returned to the Spartan alliance. In 423 they fought an indecisive battle with the Mantineans, and when the latter rebelled against Sparta and allied themselves with Argos and Athens, the Tegeans supported Sparta and played an important part in the decisive Battle of Mantinea (418). During the early 4th century Tegea continued to support Sparta against the Mantineans and others, but after the great Spartan defeat at Leuctra the Tegean pro-Spartan party was violently expelled (370) with Mantinean help.

Tegea thenceforth took an active part in the revival of the Arcadian League and in the Theban coalition against Sparta (371–362), but the foundation of the new Arcadian capital, Megalopolis, threw Tegea somewhat into the shade, and Tegea and Mantinea headed opposing parties in Arcadia in 362. In 266 Tegea joined the unsuccessful Chremonidean League against Antigonos Gonatas, king of Macedonia. It joined the Aetolian League (233) but was taken by Cleomenes III of Sparta. On his defeat it was transferred by Antigonos Doson to the Achaean League (222); it was recovered in 207 from a second Spartan occupation by the Achaean general Philopoemen. In Augustus' time Tegea was the only important town of Arcadia. It was sacked by the Goths during the invasion of A.D. 395–396 but survived.

Under the Byzantine Empire there were at least two basilicas at Tegea; that at modern Palaia Episkopi was rebuilt in the 19th century. The town came to be known as Nikli and was an important place under the Frankish princes of Achaea from 1209 until 1296, when the Byzantines regained it and moved it from the exposed plain up to Moukhli in the hills to the east. The foundation

of Tripolis (14th century) finally replaced Tegea in the area. The site is occupied by the small villages of Palaia Episkopi, in the ancient city centre, and Teyea, formerly Piali, in the southwest, on the site of the Temple of Athena Alea.

This temple was described by Pausanias (2nd century A.D.) as excelling all others in the Peloponnese. The original temple, reputedly built by the city's traditional founder, Aleus, was superseded by a larger one that was destroyed by fire in 395 B.C. Rebuilding was entrusted to Scopas, the famous sculptor, who probably provided also the pediment sculptures, representing at the front the hunt of the Calydonian boar (see MELEAGER) and at the back the battle between Achilles and Telephus. Both legends were appropriate, for the temple claimed to possess the tusks of the boar, dedicated by Atalanta, and Telephus was the son of Heracles and Auge, daughter of Aleus and priestess of Athena. It was also said that Orestes had sought asylum there; refugees from Sparta certainly did this in historical times. French excavations between 1889 and 1913 revealed the plan of Scopas' temple, 163 × 69 ft. (49.5 × 21 m.), with 6 Doric columns at the ends and 14 along the sides; like the temple at Bassae (see PHIGALIA), it had engaged Corinthian half columns inside the cella walls. Fragments of the temple, including pieces of sculptures that may be by Scopas (see GREEK ART: The 4th Century), are in the National Archaeological Museum, Athens, and the Tegea Museum. The French excavators also found traces of the ancient walls and the agora.

**TEGELEN**, a town of the southern Netherlands, in Limburg Province, is 42 mi. (68 km.) NE of Maastricht. Pop. (1960) 16,875. Both the Maas (Meuse) River, which bounds the town on the west, and the Maastricht-Nijmegen railway are used to transport goods. The town is noted for its Passion play, performed every five years, and as a pottery manufacturing centre. Other industries include iron foundries, engineering works, and manufacture of cardboard and cigars. There is also some market gardening. Tegelen belonged to the Duchy of Jülich until 1795; later it came under the French *département* of the Roer and, after 1816, passed to Limburg.

**TEGERNSEE**, a lake of West Germany in Upper Bavaria, Federal Republic of Germany, lies at 2,380 ft. (725 m.) above sea level among wooded mountains on the fringe of the Bavarian Alps, its northern end (Gmund) being about 30 mi. (48 km.) S of Munich by road or rail. The lake is about 3.9 mi. (6.2 km.) long, 0.9 mi. (1.5 km.) broad, and 3½ sq.mi. (9 sq.km.) in area, with a maximum depth of 237 ft. (72 m.). Its waters discharge through the Mangfall into the Inn. It is a much frequented summer and winter resort, with facilities for yachting and other water sports and for winter sports. Main centres are Tegernsee on the eastern shore, with the castle of the Bavarian king Maximilian I (until 1803 a Benedictine abbey, founded in the 8th century); Bad Wiessee on the western shore, a spa with iodine and sulfur springs; and Rottach-Egern on the southern shore at the foot of the Wallberg (5,650 ft. [1,722 m.]), from whose summit are views across the Mangfall Range to the Hohe Tauern, and of the Zugspitze to the southwest. About 3 mi. up the Rottach Valley is a picturesque waterfall, the Rottachfälle. (R. E. Dr.)

**TEGNER, ESAIAS** (1782–1846), the greatest Swedish poet of his age. Born at Kyrkerud in Värmland, on Nov. 13, 1782, he was thrown on his own resources by his father's death in 1792. He entered Lund University in 1799, graduated in 1802, and in 1812 was appointed professor of Greek. He continued to lecture at Lund until 1824, when he became bishop of Växjö.

Tegnér first won literary fame with his patriotic poem *Svea*, which was awarded the highest prize of the Swedish Academy in 1811. In 1812 he joined Götiska Förbundet, a romantic, nationalist league founded by Erik Gustaf Geijer and others, and between 1812 and 1813 published some of his finest poems in its periodical, *Iduna*. The solemn "Skaldens morgonpsalm" and

"Sång till solen" were particularly notable. His topical poems—e.g., "Hjälten," a tribute to Napoleon—are also remarkable. He was originally associated with the Romantic movement, but later reacted against its emotional and mystical aspect, *fosforismen*, so-called from its periodical *Phosphoros*, and represented by the work of Atterbom. "Strength and clarity" were what he demanded of poetry in the famous *Epilog vid magisterpromotionen i Lund 1820*. He had entered the Swedish Academy in 1819. His greatest poetic achievement was *Frithiofs saga*, a cycle based on an Old Icelandic saga; it became a national poem and was translated into most European languages. Other outstanding poems of this period were *Nattvardsbarnen* (1820) and the verse narrative *Azel* (1822). Eng. trans. by R. G. Latham, 1837, modeled on Byron.

The year of the publication of *Frithiofs saga* (1825) marked not only a peak in Tegnér's development as a poet but also a turning point in his life. From then on he was a sick man, and an unhappy love affair added to his suffering. He describes his state of mind in the mid-1820s in a moving poem, *Mjältsjukan* ("Melancholia"). After 1826 his duties as bishop left him little time for poetry, and yet some of his famous poems, such as "Sång den 5 april 1836" (commemorating the 50th anniversary of the founding of the Swedish Academy) and "Den döde," a love poem dedicated to a young married woman in Växjö, date from this period. He devoted special attention to education in his diocese, and his addresses at the end of the school year are of great interest. As bishop he was automatically a member of the *riksdag* and had to spend long irksome periods in Stockholm. Originally a liberal, he became increasingly conservative and entered into controversies with the successful liberal spokesmen of the time in parliament and press. These disputes and his ill-health led to embitterment. Following a stroke in 1840 he showed signs of mental disorder. During a period of convalescence he wrote "Kronbruden," an idyll in hexameters, which is his last important poem. He died at Östrabo, near Växjö, on Nov. 2, 1846.

Tegnér's poetic reputation has been confirmed by posterity. He is also regarded as Sweden's most brilliant orator and wittiest letter writer. His letters did not become widely known until his posthumous works were published by his grandson in 1873–74, at a time when the public was becoming weary of lyrical romanticism and ready to appreciate Tegnér's realistic prose style, distinguished by sparkling wit and pregnancy of expression.

An edition of Tegnér's works, by E. Wrangel and F. Böök, was published in 10 vol. (1918–25). A complete edition of his letters was begun by the Tegnér Society (1953).

**BIBLIOGRAPHY.**—G. Brandes, *Esaias Tegnér* (1878); F. Böök, *Esaias Tegnér*, 2 vol. (1946); E. Wrangel, *Tegnér i Lund*, 2 vol. (1932); A. Werin, *Esaias Tegnér. Från det eviga till Mjältsjukan* (1934). (At. Wn.)

**TEGUCIGALPA**, the capital of Honduras, was founded about 1579 on the slopes of Mt. Picacho as a gold and silver mining centre. Pop. (1961) 134,075. It alternated with Comayagua (35 mi. [56 km.] NW) as capital from 1824 to 1880, when it was made the permanent capital of the republic. In 1938 Tegucigalpa was combined with the city of Comayagüela, across the Choluteca River to the south, to form part of the Central District. The city is located on hilly terrain hemmed in by mountains at an altitude of 3,200 ft. (975 m.), with average daily temperature ranging from 65° F (18° C) in January to 75° F (24° C) in June. The dry season extends from November through April, sometimes causing severe water shortages before the rains begin, and the rainy season lasts from May through October.

One of the few capitals in the world without a railroad, Tegucigalpa depends largely on the international airport at Toncontin. Freight can be trucked in over the all-weather South Highway from the Pacific or from the adjoining republics of El Salvador and Nicaragua, but goods coming from the north must be brought by ship to Puerto Cortés, then by rail or dry-weather road to Potrerillos, and finally by all-weather road to Tegucigalpa.

The city's principal public buildings include the presidential palace, Central Bank of Honduras, legislative palace, and National University, all near the Mallol Bridge, and the cathedral, facing Morazán Park, named for the country's greatest hero. Industrial

production is small and mostly for local consumption; products include textiles, sugar, and cigarettes. (M. D. M.)

**TEHERAN** (TEHRAN), the capital of Iran and the chief city of Teheran *ostan* (province). The city is situated on the northern fringe of the central plateau, 10 mi. (16 km.) to the south of the Elburz (Alborz) mountains which skirt the southern shore of the Caspian sea. The city, which has a mean altitude of 3,800 ft. (1,158 m.), stands on ground rising gently toward the north. Pop. (1956) 1,512,082; (1965 est.) 2,620,438.

In the summer, during weekends and on public holidays, many of the citizens escape from the heat by going to the high country to the north and northeast, where there are cool resorts surrounded by magnificent mountain scenery. In winter there is good skiing on the hills above Lashkarak, 10 mi. to the northeast. The snow-capped cone of Mount Demavend, an extinct volcano (18,580 ft. [5,663 m.]); 44 mi. (71 km.) E.N.E., is visible in clear weather.

Teheran possesses few buildings of historical interest and none of any real antiquity. In the centrally situated Maidan-i-Sipah (army square) is the Shahr-dari (town hall) and nearby are various ministry buildings, the police headquarters (a modern building in Achaemenian style), and the archaeological museum which houses a most interesting collection of antiquities from Susa and other ancient sites. To the south of the Maidan-i-Sipah is the Gulistan palace (early 19th century), which is now a museum containing many objects of historical interest, including the so-called Peacock throne (see DELHI: *Old Buildings and Monuments*). Nearby, in the bazaar quarter, is the Masjid-i-Shah mosque, also dating from the early 19th century. Some distance to the east-northeast of the Maidan-i-Sipah is the Baharistan palace, in which the *majlis* (parliament) meets; it also contains a large library. Just south of the Baharistan palace is the Sepahsalar mosque, now a theological college and library. In the western part of the city is the Kakh-i-Marmar (marble palace), one of the residences of the shah; it has a tiled dome modeled on that of the beautiful Shaikh Lutfullah mosque in Isfahan. In the northwest, at Jalaliyeh, is the University of Teheran (founded 1935), the buildings of which are in a large and well laid-out garden. In the southern part of the city, at the foot of the Khaban-i-Pahlavi (Pahlavi avenue), is the large and imposing railway station. There are two public gardens, the Bagh-i-Milli, to the south of the Maidan-i-Sipah, and the Bagh-i-Shah, near the western outskirts.

**Communications and Industries.**—Teheran is the focal point of the Iranian railway system, with lines radiating to Kazvin (Qazvin) and Tabriz, to Ahvaz and thence to Khorramshahr (on the Karun river where it enters the Shatt al Arab) and to Bandar-e Shahpur on an inlet of the Persian gulf (the Trans-Iranian line), to Meshed in the east, to Bandar-e Shah, a port on the Caspian coast, and southeast to Kashan. The city is also an important road centre, as it is linked with Rasht and Bandar-e Pahlavi (formerly Enzeli) to the northwest, with Tabriz (and thence to the Soviet and Turkish frontiers), with Hamadan, Kermanshah and the Iraq frontier, with Qom, Isfahan, Shiraz and Bushire to the south, with Yazd, Kerman and Zahedan to the southeast, with Shahrud and Meshed to the east, and with the Caspian coast at Chalus to the north. The main airport is at Mehrabad, 5 mi. W. of the city, served by international airlines.

Teheran has factories for the manufacture of textiles, cement, cigarettes, sugar, glass, leather, small arms and ammunition.

**History.**—Compared with cities such as Isfahan, Teheran is of comparatively recent foundation. It is believed to have come into existence some time in the 9th century A.D., but, as it was only 5 mi. from the then large and flourishing city of Ray (*q.v.*), it remained a small and insignificant town until after the almost total destruction of that city by the Mongols in 1220. During the Safavid period (1501–1736) Teheran slowly developed into a town of medium size. In the second half of the 18th century, Karim Khan Zand was so impressed with the situation of Teheran that he sought for a time of making it his capital but eventually chose Shiraz instead. In 1785 Agha Mohammed Khan, the founder of the Qajar (Kajar) dynasty, besieged and captured Teheran and thereupon made it the seat of his government, since when it has been the capital of the country. Fath Ali Shah (1797–1834), Agha

Mohammed's successor, embellished the town, completing the Gulistan palace and erecting the Masjid-i-Shah and a number of other buildings. During the long reign of Nasir ad-Din Shah (1848–96) Teheran was largely rebuilt and grew appreciably in size. After the accession of Reza Shah Pahlavi in 1925 the process of modernization, which had already begun, was greatly speeded up. Many broad, asphalted thoroughfares were cut through congested areas, thus clearing slum districts and facilitating the flow of traffic. The development of the city is particularly noticeable in the north and northwest. Many modern buildings have been erected and those which use the Achaemenian and Sassanid styles externally have modern interiors. Between 1925 and 1955 the population increased more than sixfold. (M. A. MA.; L. Lo.)

**TEHERAN OSTAN** (or CENTRAL PROVINCE) comprises a large part of the southern slopes of the Elburz mountains (*q.v.*), a number of districts in the interior highlands, the northwestern fringe of the great central plain and part of the Daryacheh-ye-Namak desert. The province is divided into the *shahrestans* of Teheran, Karaj, Qazvin, Damavand, Mahallat, Saveh, Qom, Tafresh, Rey, Shemiranat, Garmsar and Khomeyn. Pop. (1956) 2,874,511; area 36,139 sq.mi. (93,600 sq.km.).

Teheran *ostan* is the focal point of Iran's chief roads and railways. About a third of the country's industries are located there, the chief being the manufacture of consumer goods, sugar refining, textiles, coal mining, iron founding and the production of munitions and cement. The province is connected by oil pipeline with Abadan refinery and with the new oil field of Alborz near Qom. The Karaj and Latiyan dams provide a water supply for Teheran as well as electric power and water for irrigation. (H. Bo.)

**BIBLIOGRAPHY.**—Sir Herbert Thomas, *Travels in Persia, 1627–1629* (1928); Guillaume-Antoine Olivier, *Voyage dans l'Empire Othoman, l'Egypte et la Perse* (1807); L. Lockhart, *Persian Cities* (1960).

**TEHUANTEPEC, ISTHMUS OF** (ISTMO DE TEHUANTEPEC), lies between the gulfs of Campeche and Tehuantepec, with the Mexican states of Tabasco and Chiapas on the east and Veracruz and Oaxaca on the west. It includes a part of Mexico lying between the 94th and 96th meridians of longitude west. The isthmus is 137 mi. (220 km.) across at its narrowest part from gulf to gulf, and 120 mi. (193 km.) from the Gulf of Campeche to the head of Laguna Superior, an inlet of the Gulf of Tehuantepec. The Sierra Madre breaks down in the isthmus into a broad, plateaulike ridge, whose elevation, at the highest point reached by the Tehuantepec railway (Chivela pass), is 781 ft. (238 m.). The northern side of the isthmus is swampy and densely covered with jungle. The whole region is hot and malarial except on the open elevations where Pacific winds render it comparatively cool and healthful. The annual rainfall on the Atlantic or northern slope is 48 in. (1,219 mm.) and the maximum temperature about 35° C (95° F) in the shade. The Pacific slope has a drier climate.

Since the days of Hernán Cortés, the Tehuantepec isthmus has been considered a favourable route, first for an interoceanic canal and later for an interoceanic railway. Its proximity to the axis of international trade gave it some advantage over the Panama route, which was counterbalanced by the narrower width of Panama. When the great cost of a canal across the isthmus compelled engineers and capitalists to give it up as impracticable, numerous projects for the construction of a railway were initiated. The railway was finally opened to traffic in 1907; it is 192 mi. long, extending from Puerto México on the Gulf of Campeche to Salina Cruz on the Gulf of Tehuantepec. There are rail connections to Veracruz, Mexico City, and the Guatemalan border. Salina Cruz is a free port with large dry docks. The town of Tehuantepec is the centre of the distinctive Tehuanas, whose social organization is matriarchic. The Tehuana women are noted for their beauty and for their colourful fiesta dress. (J. A. Cw.)

**TEHUELICHE**, an effectively extinct Indian tribe once occupying the plains of Patagonia (*q.v.*) from the Río Negro to the Strait of Magellan. Their great stature and physical vigour created a giant tradition in European literature. Since the arid, windswept nature of Patagonia made agriculture unprofitable, the

Tehuelche were nomadic hunters. Before the 16th century they lived much as did their kinsmen the Ona (q.v.) in Tierra del Fuego, but the introduction of horses by Europeans greatly enlarged their sphere of action and culture. By the 1960s their survivals were largely linguistic.

See T. Caillet-Boys, "Extinction of the Tehuelche Indians," *Geogr J.*, vol. 103 (1944); J. H. Steward (ed.), *Handbook of South American Indians*, 7 vol. (1946-59).

**TEILHARD DE CHARDIN, PIERRE** (1881-1955), French Jesuit paleontologist and thinker whose originality of aim and method invites comparison with that of such devout pioneers as Pico della Mirandola, Ramon Llull, or even Origen, was born on May 1, 1881, at Sarcenat, near Orcines, Puy-de-Dôme. Having acquired from his father a habit of keen observation and an interest in geology, he was sent in 1892 to the Jesuit College of Mongré, at Villefranche-sur-Saône. In 1899 he joined the Jesuit noviceship at Aix-en-Provence.

© PHILIPPE HALSMAN

TEILHARD DE CHARDIN

Because of the expulsion of the Jesuits from France, his subsequent studies were carried out in Jersey (1901-05) and finally, after an interval of teaching in Cairo (1905-08; during which time he carried out his first explorations in the Fayum), at Hastings in England, where he was ordained priest in 1911. He then studied paleontology under Marcellin Boule at Paris (1912-14). He served during World War I as a regimental stretcher-bearer (battles of Ypres, Verdun, Chemin des Dames and the Marne) with the rank of corporal, though he was offered the post of chaplain with the rank of captain. He taught at the Institut Catholique in Paris for some years but soon began his visits to China, where in December 1929 he was concerned in the discovery of an exemplary specimen of Peking man (*Sinanthropus*). Further travels took him to the Gobi Desert, Sinkiang, Kashmir, Java, and Burma. He spent 1939-46 at Peking in near-captivity. After World War II he returned to Paris. In 1951, however, making a detour by way of South Africa, he went to the United States to spend the rest of his life with research teams there (apart from another visit to South Africa in 1953). He died in New York on April 10, 1955.

Most of Teilhard's writings were scientific, and especially concerned with mammalian paleontology. His philosophical books were the product of long meditation: *Le Milieu divin* appeared in 1926-27 (Eng. trans. 1960); *Le Phénomène humain* in 1938-40 (Eng. trans. *The Phenomenon of Man*, 1959). His *Lettres de voyage* (1923-39) and *Nouvelles lettres de voyage* (1939-55), collections of correspondence and reminiscences, were published in English as *Letters from a Traveller* (1962). The letters he wrote to his cousin Marguerite during his 4½ years in the army were collected as *The Making of a Mind* (1965). *L'Apparition de l'homme* (1956; *The Appearance of Man*, 1965), *La Vision du passé* (1957; *The Vision of the Past*, 1966), and *Science et Christ* (1965) consist of essays put together for the collected edition of Teilhard's works. Officials of his order regarded Teilhard's later intellectual musings as exceeding the bounds of priestly reflection and banned their publication during his lifetime. He aimed at a metaphysics of evolution, holding (against Bergson) that it was a process converging toward a final unity (Teilhard's "omega point").

The Aristotelian idea that material objects tend to seek their natural places fell victim to the astronomy of Galileo, and the bifurcation of nature (duality of body and spirit) introduced by Descartes banished intrinsic finality completely from the material world. Teilhard shows that what is of permanent value in traditional thinking can be maintained and even integrated with a modern scientific outlook if one accepts that the tendencies of

material things are directed, either wholly or in part, beyond the things themselves toward the production of more complex, more perfectly unified beings that can rightly be called higher. In place of the Darwinian-Spencerian "survival of the fittest" Teilhard espouses "survival of the more complex." He regards basic trends in matter—gravitation, inertia, electromagnetism and the like—as being ordered toward the production of increasingly complex higher types of aggregate.

To Teilhard, living things are directed by two tendencies simultaneously: inwardly toward self-perfection (called radial energy) and outwardly—away from the individual and its species—toward biological evolution (called tangential energy). Both types of energy he regards as "psychic," though admitting that between the tendencies of nonliving and of living things there is not identity but only analogy. He uses analogy again to compare the first appearance of life on earth (still a great mystery) with the appearance of man. While some evolutionists regard man simply as a prolongation of the Pliocene world—an animal more successful than the rat or the elephant—Teilhard argues that the appearance of man brought an added dimension into the world. This he defines as the birth of reflection: animals know, but man knows that he knows; he has "knowledge to the square."

Another great "mutation" in Teilhard's scheme of evolution is the socialization of man. This is not the triumph of herd instinct but a cultural convergence of humanity toward a single society. Love in this scheme is the highest radial energy; it makes a man more of a person (and so more perfect) because and not in spite of the fact that it binds him more closely to his fellows: union differentiates. Evolution has gone about as far as it can to perfect man physically: its next step will be social. Such evolution is currently in progress. Between peoples—in economics, in politics, and in habits of thought—more and more links are being established in something like a geometric progression. What may look like servitude, leveling, and ugliness hides growth in complexity and reflection. Man is approaching his final development; there is a convergence.

Theologically, Teilhard sees concurrent convergence toward an omega point in organic evolution (a final state, at present hypothetical) and a true omega point in Christian revelation, usually described as the Parousia, or second coming of Christ. Christianity is "a phylum of love within the world of nature"; it unites men into a mystical body that is more than a social or moral union: "Christ has attributes universal and cosmic, and these constitute him the personal omega point that is hypothetically invoked by the metaphysics of evolution." Teilhard's thought was Christocentric, following that of his teachers Léonce de Grandmaison and Joseph Huby. His ideas of cosmic redemption revived what the Early Christian Father Irenaeus had written on the recapitulation of all things in Christ. From the medieval philosopher Duns Scotus, Teilhard took the idea that the work of Christ is primarily to lead creation to fulfillment and to be its own crown, while the conquest of evil is only secondary to his purpose. Although claiming a pre-established harmony between the evolutionary tide as observed by science and the teaching of the Christian revelation, Teilhard shows the complete gratuity of the latter and thus avoids falling into pantheism.

Evil is represented by Teilhard as growing pains within the cosmic process: the disorder that is implied by order in process of realization. This does not take account of sin as a failure of love, and has been criticized as the blind spot in Teilhard's thinking. Looking at death in the light of Christ's resurrection, Teilhard calls it a mutation that frees the individual from entropy and allows him growth in radial energy without a corresponding expenditure on tangential energy. It might appear that Teilhard never fully worked out the relation of this mutation (death)—which is in store for each individual—to the mutation from individual life to corporate life, a jump that appears to be imminent for humanity as a whole.

tery of Christ (1966). Books and articles about Teilhard are listed annually in *Archivum historicum Societatis Iesu*. (J. H. CN.)

**TEISSERENC DE BORT, LEON PHILIPPE** (1855–1913), French meteorologist, noted for his discovery of the stratosphere, was born in Paris on Nov. 5, 1855, the son of an engineer. He began his scientific career in 1880, when he entered the meteorological department of the Central Bureau of Meteorology in Paris under E. E. N. Mascart. In 1883, 1885, and 1887 he made journeys to North Africa to study geology and terrestrial magnetism, and during that period published some important charts of the distribution of barometric pressure at a height of 4,000 m. In 1892 he became chief meteorologist to the bureau but resigned in 1896 and founded a private meteorological observatory at Trappes, near Versailles, where he carried out investigations on clouds and the problems of the upper air. In 1898 he published an important paper in *Comptes Rendus* detailing his researches by means of balloons into the constitution of the atmosphere. His discovery of the so-called isothermal layer, or stratosphere, will always stand out as one of the most important events in the study of the upper atmosphere. (See also BALLOON FLIGHT.) He also carried out investigations in Sweden and over the Zuider Zee, the Mediterranean, and the tropical region of the Atlantic. He died at Cannes on Jan. 2, 1913.

**TEITA** (TAITA), a Bantu-speaking people numbering 60,000 (1960s) mainly in the Teita Hills of southeastern Kenya (*q.v.*). These agriculturalists call themselves and their language Dabida. Their chief crop is maize, but they also grow vegetables and bananas for market in Mombasa by irrigating through furrows and pipes of banana stems. Cattle, goats, and sheep are valued for exchange and sacrifice. Many Teita work in Mombasa; others are found as labourers throughout east Africa. The tribe is grouped into seven patrilineal dispersed clans (*vichuku*). A clan segment, a lineage (*kivalo*) of about four generations, is the basic social unit. These lineages are formed into districts, the major modern administrative units. Men initiated together form an age set (*q.v.*); elders of senior sets are members of councils, presided over by district headmen. There has been a relatively recent development of tribal associations, some of which have been strongly nationalistic and politically active. Worship is directed toward propitiation of ancestral and community powers; in tribal crisis, the skulls of the forebears are offered a sacrifice of sheep, oxen, and beer (women are excluded from this ritual; in others they can be priestesses).

See A. H. J. Prins, *The Coastal Tribes of the North-Eastern Bantu* (1952). (J. F. M. M.)

**TEKAKWITHA** (TEGAKWITHA, TEGAKOUITA), **KATERI** (1656–1680), the first North American Indian ever presented to Rome for sainthood was born probably at Ossernenon (Auriesville), N.Y., in 1656. Her father, a pagan Mohawk chief, her mother, a Christian Algonkian, and her brother died of smallpox when she was four. The disease left her with pitted skin, poor eyesight, and damaged health. Staying with her anti-Christian uncle, she was deeply impressed at the age of 11 by the lives and words of three passing Jesuits, the first Christians she had spoken to. For years she refused marriage proposals and virtuously performed drudgeries common to squaws. At 20 she was instructed in religion and baptized Katherine by the Jesuit Jacques de Lamberville, who had been astonished at her knowledge and practice of Christian ideals. In her home village she was jeered, stoned, calumniated, and threatened with torture. She narrowly escaped death by fleeing 200 mi. through forests to the Christian Indian mission of St. Francis Xavier at Sault St. Louis near Montreal. There in summer she toiled in the fields and during the winter hunts she carried heavy loads. Practising her faith heroically in suffering, prayer and kindness, she merited the title "Lily of the Mohawks." She died at the age of 24, on April 17, 1680. Her practice of heroic virtue was recognized by the Sacred Congregation of Rites in 1943.

See *Positio of the Historical Section of the Sacred Congregation of Rites on the Introduction of the Cause for Beatification and Canonization and on the Virtues of the Servant of God, Katherine Tekakwitha, the Lily of the Mohawks* (1940). (J. V. J.)

**TEKIRDAG**, a town and capital of the *il* (province) of the same name in European Turkey, lies on the Sea of Marmara, 78 mi. (126 km.) W of Istanbul. Pop. (1965) 26,964. It is an important market centre for agricultural products. A main road links the town with the Istanbul-Uzunkopru railway at Muratli.

A Greek settlement founded probably in the 7th century B.C., the town was originally called Rhaedestus or Bisanthe, and later Rodosto. Since 1923 it has been officially known under its Turkish name of Tekirdag ("prince's hill"). Rodosto was for centuries the port of the Adrianople (Edirne) area, but its trade suffered when Alexandroupolis (Dedeagatch), on the Aegean Sea, became the terminus of the railway up the Maritsa River. The town was conquered by the Turks in 1360; it was occupied successively by the Russians (1877–78), the Bulgars (1912), and the Greeks (1920–22). The Greek church of Panagia Rheumatocratisa contains the graves, with Latin inscriptions, of Hungarians banished from their country early in the 18th century by the German captors of Buda. The population of Tekirdag in 1914 was estimated at 25,000, half of it Greek. In 1927, after the Greek-Turkish exchange of populations, Tekirdag had only 14,569 inhabitants.

TEKIRDAG IL (area 2,401 sq.mi. [6,218 sq.km.]; pop. [1965] 286,714) is one of the most important wine-producing areas of Turkey, and a large quantity of wine is exported.

(N. TV.; S. ER.; E. TV.)

**TEKTITE**, the name given by F. E. Suess (from the Greek *tektos*, "melted"), for the natural glass objects found in various parts of the world and thought to be either meteorites or the result of impact on earth by meteorites, asteroids or comets. They range in weight from less than a gram to about eight kilograms and are of varied colour, shape and surface sculpture. Most are black, some are green, a few are yellow. Some are lustrous and some have a delicate sheen from minute alternating ridges and furrows which swirl over the entire surface, following the contorted internal structure. The younger, less-corroded tektites include spherical, elliptical, lenticular, teardrop, dumbbell, disk and button forms. They have been used as charms or amulets; and in folklore were regarded as an index of the richness of alluvial gold and tin deposits in which they are often found.

Tektites came to rest in groups at widely different times in the earth's history, with none arriving in between. They range from a few thousand years old (Australia) to about 50,000,000 years old (Texas). They are known on every continent except Antarctica and South America and are usually given distinctive names according to where they are found. Among these names are mol-davites (Bohemia), australites, billitonites and javanites (Indonesia), indochinites, philippinites, bediasites (Texas), Darwin glass (Tasmania) and Libyan desert glass. They are known from the Ivory Coast and Georgia (U.S.). The americanites from Colombia and Peru, originally believed to be tektites, are now known to be volcanic glass. The button form of australite, showing two periods of melting, furnishes strong evidence that tektites came from outside the atmosphere. Such a form can be explained only if a sphere of glass plunged into our atmosphere. It would melt on the forward side, the area of greatest friction, but as the fragment slowed, some melt would flow toward the lee and curl to form a flange. There is equally strong evidence that most tektites formed from soil and sedimentary rocks like those on earth. Sand-size glass particles in tektites, identified by Virgil E. Barnes as lechatelierite (fused quartz), have a consistent earthly counterpart only in the quartz of sandy and shaly sedimentary rocks and soil (see SILICA: *The Silica Minerals*). Chemically, tektites are more closely related to sandy and shaly sedimentary rocks than to any other rock group. Because of this G. Linck believed tektites came from another planet blanketed by sedimentary rocks.

In 1962 it was found that puddlelike deposits of layered indochinites in Southeast Asia are related in their gross chemical aspects both to the associated soil and underlying sedimentary rock, and to splash-form indochinites. A growing volume of isotopic and other chemical data also support the origin of tektites mostly from soil. Detrital quartz grains, identical in size and shape to those in the soil and sedimentary rock on which tektites

rest, have been identified in layered tektites from Thailand. Some of these quartz grains were altered to coesite, one of the high-density forms of silica produced by high pressure. Coesite (q.v.) is found in association with meteorite impact craters.

L. J. Spencer thought tektites might be formed from meteorite impacts on earth. Harold C. Urey in 1955 suggested that the impacting bodies might be asteroids, but in 1957 proposed that shock waves from comets might be a more logical means for their formation. If the button form was produced by impact or shock waves, then molten glass must have been ejected beyond the atmosphere to solidify, before plunging back into the atmosphere.

See also METEORITES: *Glass Meteorites*; GEOCHEMISTRY: *Meteorites and Geochemistry*. (V. E. B.)

**TEL AVIV-JAFFA**, a twin city of Israel on the Mediterranean Sea, 47 mi. (76 km.) NW of Jerusalem by road, is the communications and commercial centre of the country and also a principal cultural centre. Jaffa (Yafo, Japho, Joppa, [q.v.]) is an ancient port, dating back possibly to 2000 B.C.; Tel Aviv is a new creation founded in 1909 by Zionist settlers on the sand dunes north of Jaffa. In the British mandate period (1923–48) there were two municipalities, but in 1950 Jaffa was incorporated with Tel Aviv. The combined population (1961) was 386,070. The municipalities of Ramat Gan, Holon, and Bnei Brak are satellite towns; and the total population is more than 600,000.

The principal streets of Tel Aviv are Allenby Road (1918), running from the city centre toward the shore, and a series running south to north parallel with the shore, the chief being Yarkon, Eliezer Ben-Yehuda, Dizengoff, and the Rothschild Boulevard. The town has constantly extended northward and nearly half the municipal area is now north of the Yarkon River, which in the mandate period was the boundary. In Arab Jaffa the main streets were Butros (Peter), close to the seashore, and King George V Avenue (now Jerusalem Boulevard), laid out in 1927 to link the suburbs of the two towns. Important buildings in Jaffa are the municipality and the district government offices, damaged in the War of Independence, the Russian Orthodox Church, St. Peter's Monastery (Franciscan), and the English church. In Tel Aviv the Great Synagogue, the chief banks and commercial buildings are in Allenby Street. There are more than 400 synagogues (many are just rooms) in the municipal area.

The original nucleus of Tel Aviv was the Herzlia *Gymnasium*; the original Museum of Art was the house of Meir Dizengoff, the first mayor. Beside it a new art gallery, bearing the donor's name Helena Rubinstein, was dedicated in 1959 in the civic centre, which also includes a modern concert hall; the Temple of Culture built in 1957; and the Habima (q.v.) Theatre, home of the national dramatic company, opened in 1945. The Mograbi cinema in Allenby Street was formerly the principal auditorium for operas and concerts. In the northern suburb rises a vast pile, the offices of the Labour Federation (Histadrut), and popularly known as the Kremlin. Near it are the centre of the Zionist Organization of America and a journalists' and writers' club. Most of the country's daily newspapers and periodicals are published in the town. The parks are small since, before the establishment of the state, Tel Aviv was congested because of the great cost of land. They include a zoo and a botanical garden. A school of law and economics, established with municipal help in the mandate period, became in 1959 a branch of the Hebrew University of Jerusalem. University colleges of arts and science were subsequently founded and form the University of Tel Aviv. The Labour Federation is active in promoting adult education, and maintains two residential colleges, and an Afro-Asian institute providing courses in economic and social sciences for students from Africa and Asia. There are, too, an academy of music, several teachers' training colleges, and a broadcasting station.

The main urban and interurban transport service is provided by buses run by cooperative societies. Service taxis (Sherut), in which the passenger pays for a seat, ply along the main thoroughfares and also between the towns. There are two railway stations: one in the northern outskirts for the line to Haifa; the other near the commercial centre, connecting with Lydda and Jerusalem. Tel Aviv is the centre of the road system of the whole country.

Tel Aviv and Jaffa have a combined port, stretching from the mouth of the Yarkon River to the promontory of old Jaffa, and used almost entirely for freight, not for passengers. The main industry since the establishment of the state has been construction. There are no heavy industries, but light industries of many kinds flourish—textile, furniture, foodstuffs, pharmaceutical. Tel Aviv is the principal banking and insurance centre of Israel. Citrus fruit from the southern region is the main export, but most of the fruit passes through Haifa.

For the history of the city, see JOPPA.

**TELEGRAPH** (Gr. *tele*, "far"; *graphein*, "to write"), a system of communication at a distance through the medium of electromagnetic phenomena, in which the information transmitted is in (or may signify) written, printed or pictorial form. (No. B.)

The evolution of telegraphy may be traced from the signaling methods and codes of the ancient and primitive peoples to the visual system of Claude Chappe and thence with the growth of scientific knowledge to the first commercial application of electricity and magnetism to the "electric telegraph." Development in the mid-19th century provided the public with the only rapid means of communication until the advent of the telephone, which led to a continuous decline of public telegraph traffic within national boundaries during the 20th century. However, the continued development of telegraph technique evinced particularly in the teleprinter and improved transmission methods has enabled operation to be delegated to its users in certain fields. Public exchange service that gives direct printing communication between subscribers nationally and internationally is increasing rapidly. Many organizations—commercial, transportation, press and government—operate private networks for their internal business traffic. The high information density that can be carried telegraphically and the overwhelming value of the printed record provide a service that cannot be given by the telephone. See also FACSIMILE TRANSMISSION.

This article, which traces the development of telegraphy, is divided into the following sections:

- I. Historic Telegraphs
- II. Direct-Current Transmission Circuits
- III. Telegraph Codes
- IV. Machine Telegraphs; Exploitation of Circuit Capability
- V. Printing Telegraphs
- VI. Line Plant
- VII. Transmission Theory
- VIII. Telegraph Switching
- IX. Submarine Telegraphy
- X. Radio

## I. HISTORIC TELEGRAPHS

**Pith Ball and Spark.**—Sir William Watson in England demonstrated in 1747 that an electric current could be transmitted through a considerable length of wire using the earth for the completion of the circuit. In 1753 the first suggestion for an electrical telegraph was made in Scotland by an anonymous writer to *Scots Magazine*, signing himself C. M., who advised using an insulated wire for each letter of the alphabet. At the receiving end of each wire a pith ball was to be suspended above a piece of paper marked with an alphabetical letter. As a charge was sent along a given wire, the ball would attract the paper beneath it, and thus words could be spelled out. He further suggested that bells might be substituted for the papers, which could be struck in turn by a ball as a charge was sent along a wire. The idea was carried out by Georges Louis Lesage in Geneva in 1774, and similar telegraph systems were suggested by Bétancourt and Lomond in 1787. Then followed other suggestions using a separate wire for each letter. by Reusser, or Reisser, in 1794, and by Francisco Salvá in 1798. Each of them proposed a system of visual telegraphy by causing a spark to appear at a gap at the receiving end of each wire as desired.

Sir Francis Ronalds worked a telegraph in England in 1816 with transmitting and receiving apparatus consisting of circular plates on which were inscribed letters and figures. In front of each plate was a disk with an aperture which allowed one letter and its corresponding figure to be visible. The plates were rotated by clock-

work regulated so that the same letter was displayed simultaneously at both ends. A crude electric machine charged the line when the sender desired, and the divergence of a pair of pith balls at the receiving end indicated to the operator that the letter or figure appearing at that moment was to be recorded.

Toward the end of the 18th century, Luigi Galvani and Alessandro Volta conducted experiments which revolutionized preconceived ideas of electricity and its effects. In 1786 Galvani accidentally discovered that it was possible to cause a direct or continuous flow of current along an electrical conductor by bringing two dissimilar metals into contact with a moist substance. In 1800 Volta introduced an electric battery which became known as the voltaic pile, the principles of which became embodied in the modern battery, and in that year Salvá demonstrated that voltaic currents could be used for transmitting signals.

**Electrolytic Telegraphs.**—An immediate result of the introduction of the voltaic pile was the discovery by William Nicholson and Sir Anthony Carlisle in 1800 that the passage of an electric current caused decomposition of liquids into their constituent elements.

Based on this principle Salvá in 1805 and Samuel Thomas von Soemmerring in 1809 introduced apparatus in which a voltaic pile was used for sending signals whose presence was indicated at the receiving end by the liberation of hydrogen. Later researches by Sir Humphry Davy on the decomposition of chemical compounds by electric current were applied in the United States to another type of telegraph by John Redman Coxe in 1816 and Harrison Gray Dyar in 1828. Both Coxe and Dyar operated a telegraph using the electric current to produce electrical decomposition at the end of the conductors. Dyar operated his telegraph line over 8 mi. on Long Island, using a single wire with ground return circuit to mark coded signals on a moving strip of litmus paper by discoloration from the received electric current.

**Electromagnetic Needle.**—At the beginning of the 19th century, a new set of ideas followed the introduction of the electromagnet. In 1819 Hans Christian Oersted discovered that a magnetic needle could be deflected from its normal position by passing a current through an adjacent wire and that the deflection was to the right or left, according to the direction of current. A year later Johann Salomo Christoph Schweigger found that the deflection of the needle could be increased by surrounding it with a number of turns of wire, and in 1825 William Sturgeon in England produced and named the electromagnet.

The action of the electric current on a magnet was first applied to telegraphy by André Marie Ampère in 1820, at the suggestion of Pierre Simon Laplace that the deflections of small magnets placed at the receiving ends of 26 wires could be used to indicate the letters of the alphabet. Ampère's apparatus was the pioneer of many needle instruments which came into existence between 1829 and 1841. The names of Carl Friedrich Gauss and Wilhelm Weber, Sir William Fothergill Cooke and Sir Charles Wheatstone,

and the brothers Highton (Henry and Edward) are associated with some of the more important needle instruments.

In 1831 Joseph Henry (*q.v.*) constructed and successfully operated an electromagnetic signaling apparatus which consisted of a magnetized steel bar supported on a pivot in a horizontal position, which could be attracted by a magnet. When the magnet was energized by current the extremity of the bar was caused to strike a bell, and intelligence was conveyed by coded sound combinations.

Gauss and Weber conducted important experiments in 1833 on line conductors in which they demonstrated that the line conductor need not be insulated over its entire length. They used a single-needle telegraph to communicate with each other and proved that, by proper combination, five signs are sufficient for communication. In the early experiments of Cooke and Wheatstone, five wires and five needles were employed but later were reduced to one of each. In the single-needle instruments a magnetic needle was pivoted in the centre of a wire coil and intelligence was transmitted by deflecting it in accordance with a prearranged code.

The name of Samuel F. B. Morse, a U.S. artist and later professor of natural science at Yale university, is universally associated with the telegraph as result of his invention of the code bearing his name. From 1850 to the 1920s Morse was the code most generally used and, in its cable code form, is still in use. He is often credited with the invention of the telegraph on his return to the United States from a trip to Europe in 1832, during which he became acquainted with the works of Michael Faraday, but he definitely produced a telegraph instrument that was exhibited in 1837. The transmitter comprised a comb (or "portrule") with "teeth" spaced at intervals in conformity with a code. The comb was passed beneath a contact lever so that it made and broke an electric circuit. The pulses of current passed through an electromagnet, causing it to deflect a lever carrying a pencil, thus producing an undulating line on a paper tape moved by clockwork to record the signals received.

In a practical application of these ideas Alfred Vail, an associate of Morse, discarded the "portrule" in favour of a simple hand-operated contact lever or key, and it was later found that the signals could be reliably interpreted by ear from the sound of the movements of the electromagnet armature. Recording was also discarded, not to be revived until much later. After initial government support a full-scale demonstration between Washington, D.C., and Baltimore, Md., was given in 1844, but when this support was withdrawn other sources were enlisted to form a company in 1845.

In England public interest in Cooke's and Wheatstone's developments was growing in the same period, and the Electric Telegraph company was formed in 1845.

## II. DIRECT-CURRENT TRANSMISSION CIRCUITS

**Simplex.**—The elementary telegraph circuit consists of a contact device (a "key," if hand operated) that makes and breaks the connection between a source of current (*e.g.*, a battery) and the line, according to the signaling code, and the pulses of current passing to the distant end of the line actuate the receiving device; *e.g.*, a "sounder" if aural reception is required. Alternate transmission of messages in both directions along the line may be made by suitable connections of instruments, and intermediate stations may be connected.

Two general schemes have been employed: in one, during the idle condition, no current flows in the line (fig. 1[A]); in the other, the closed-loop system, current flows in the line (fig. 1[B]). In the latter, as shown, a send-receive switch must be operated before sending can take place, but an alternative connection can be used in which the free contact of the transmitter can serve this purpose automatically.

Instead of single-current (on and off), double-current (current reversal) signaling may be used with definite advantage (fig. 2). Although it requires a polarized receiver (one sensitive to current direction rather than current strength), variations in line characteristics have less effect and entail less frequent adjustment of the receiver. At terminal stations a double battery

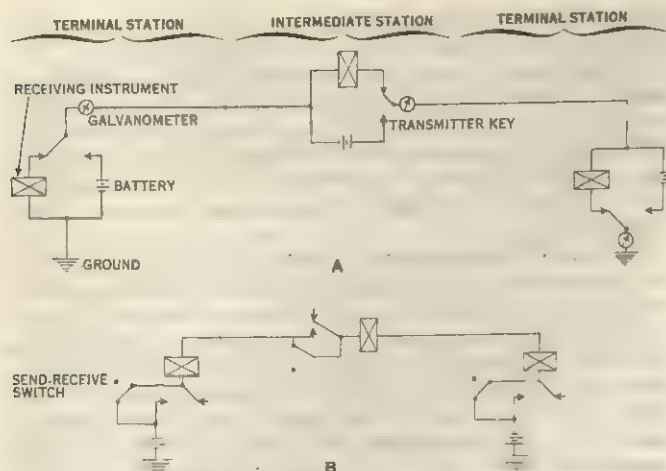

FIG. 1.—TWO SIMPLEX TRANSMISSION SCHEMES IN IDLE CONDITION: (A) SINGLE-CURRENT CIRCUIT, IN WHICH NO CURRENT IS FLOWING; (B) CLOSED-LOOP SYSTEM, IN WHICH CURRENT IS FLOWING

is usual, but at intermediate stations a single battery with a commutating key would be used.

**Duplex.**—The duplex scheme, permitting simultaneous transmission in both directions between two terminal stations, was first proposed in 1853 by Wilhelm Gintl. The principle is the interconnection of the transmitting and receiving devices with the line and a balancing network, so that the receiver is unaffected by the sending current from its own station but responds to the operation of the distant transmitter. It is usual for double-current signaling to be employed. The differential form (fig. 3)

FIG. 2.—SIMPLEX CIRCUIT FOR DOUBLE-CURRENT (CURRENT-REVERSAL) SIGNALING

uses a receiver or relay with two identical windings connected so that the current from the transmitter divides to produce opposing magnetic effects, part flowing into the line and part into the balance or artificial line, which is adjusted so that the magnetic effects of the currents in the two paths balance to produce no resultant effect on the receiver. The changes in line current due to the action of the distant transmitter produce an unbalanced effect in the windings of the receiver, which responds accordingly. Bridge duplex (fig. 4) utilizes a receiver or relay with a single

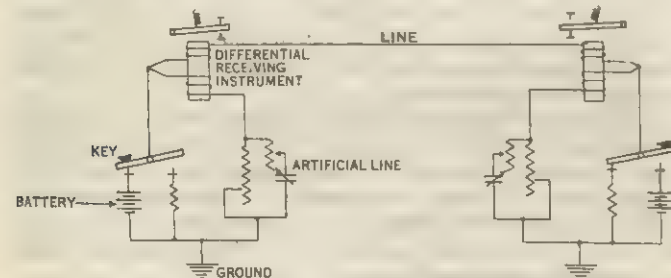

FIG. 3.—DIFFERENTIAL DUPLEX CIRCUIT

winding connected across one diagonal of a Wheatstone bridge circuit formed by two equal impedances, the line and the artificial line. When the artificial line is accurately adjusted to simulate the electrical characteristics of the line, the operation

of the transmitter, which is in the other diagonal of the bridge produces no change in electrical potential across the receiver and hence no response.

**Quadruplex.**—To increase further the message capacity of a

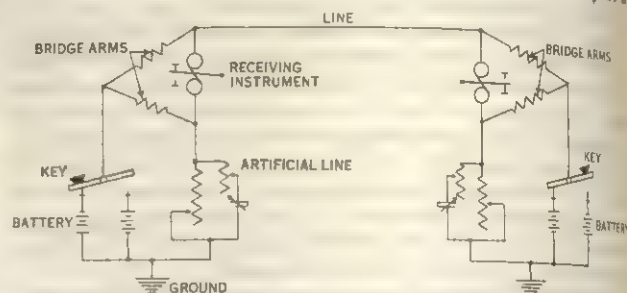

FIG. 4.—BRIDGE DUPLEX CIRCUIT

single telegraph circuit, Thomas A. Edison produced a combination of double-current and modified single-current duplex, providing for the transmission of two messages in each direction simultaneously. Two receiving devices are used, one polarized and responding to the direction of current, the other nonpolarized and responding to change in current magnitude irrespective of direction. With the development of other transmission methods, this system was discarded.

In modern practice, except for submarine cable usage, direct-current transmission is employed usually only over distances up to 100 mi. Both single- and double-current simplex methods are used in different areas of the world. With the single-current method, the closed-loop system, without send-receive switches and using a return conductor in place of earth, with one current source in the loop, is general. In the double-current method, the simple arrangement of two lines, one for each direction of transmission to avoid switching of transmitters and receivers and with no intermediate stations, is usual.

**Derived Circuits.**—Direct-current telegraph circuits may be derived from, and worked simultaneously with, telephone circuits by superposition. Superposing permits one ground-return telegraph circuit to be operated over the two wires forming a metallic-return telephone circuit. In a common form (fig. 5) a repeating coil or transformer is interposed at each terminal between the telephone apparatus and the line. The transformer winding which is connected to the line wires has a centre tap connected to the telegraph apparatus. By this arrangement the telegraph currents are divided, half passing over each wire; no effect is produced upon the telephone apparatus because, in dividing equally, the two halves neutralize each other's magnetic effect. The alternating currents of the speech transmission so traverse the line windings of the transformer as to cause the maximum magnetic effect and are thus repeated to the telephone apparatus.

**Telegraph Repeaters.**—With increasing length of a telegraph line, the received current becomes weakened so that eventually it will not operate the receiving device reliably. It was first appreciated by Edward Davy that a relay could be used to repeat signals from one line to another, the armature of an electromagnet operating contacts to send the signals anew with the original current strength. Hence by dividing a line into sections and inserting repeaters between each section, the signals can be re-

FIG. 5.—SIMPLEX CIRCUIT FOR TELEGRAPH TRANSMISSION ON TELEPHONE LINES

newed in magnitude before they deteriorate to an unusable level. In the direct-current transmission circuits described above, re-

printers can be formed by making the receiving device a relay and connecting the armature or tongue to the adjacent line in place of the transmitter, the transmitting battery being connected appropriately. In the case of the closed-loop circuit, additional relays must be used in connections to prevent signals from being fed back into the line from which they were received.

Distortion of signals takes place in transmission such that, although they can be restored in magnitude by a relay, the relative timing of the signal elements is disturbed and retransmission over a further section would render them liable to faulty interpretation. In machine telegraph transmission at a regular speed, regenerative repeaters can be employed to receive and retransmit the signals with all the elements restored to a perfect time relationship. This is done by automatically examining the instantaneous condition of the incoming signal at unit element intervals in correct phase and maintaining this condition on the outgoing line until the next instant of examination.

### III. TELEGRAPH CODES

The best-known code is the Morse Code (fig. 6). It was the most generally used until about the mid-1920s and is still used in a modified form on some submarine cable systems and radiotelegraph circuits and in some situations where mobile stations with simple apparatus are required. The code comprises combinations of dots and dashes of one line condition (e.g., current on) separated by periods of the other line condition (e.g., current off); the duration of a dot is taken as one unit, that of a dash three units; the space between character components is one unit, between characters three units and between words six units (five for automatic transmission).

the most widely adopted by mid-20th century. Five units with two-condition signaling provide 32 permutations, sufficient for the Roman alphabet and (by using two permutations as case-shift signals) figures, punctuation signs and the control of certain essential mechanical functions of a printing receiver. For certain special applications, a six-unit code that avoids the use of case-shift signals is used.

Since all permutations of the five-unit code are significant, an error in the reception of any signal element will result in a wrong character being recorded. So that faulty reception can be detected, particularly after transmission over circuits liable to severe disturbance (e.g., long-distance high-frequency radio), a seven-unit code was devised by J. B. Moore which permitted the detection of mutilation. In a modified form proposed by H. C. A. Van Duuren, its use rapidly spread (fig. 7). Seven units provide 128 permutations, only 35 of which are used to signify characters. Reception of any of the others indicates mutilation in transit. The 35 permutations possess the common characteristic of having three elements of one kind and four of the other.

### IV. MACHINE TELEGRAPHS; EXPLOITATION OF CIRCUIT CAPABILITY

With the commercial development of the telegraph in the late 1840s it became obvious that the manual sending methods of forming the code signals directly were unable to exploit the full capabilities of the transmission lines, and attention of many in-

ventors was turned to increasing the speed of signaling and providing more convenient means of generating and recording signals.

**Wheatstone System.**—The Wheatstone system (1838) employed perforated tape to operate the transmitting mechanism, which was driven by clockwork and later by electric motor. The Morse signals were received by an "inker" in which an inked wheel marked the dots and dashes on a moving tape. When first brought into use in the 1860s the system was capable of about 70 words per minute, but by the early 1900s it had been developed to 300–400 words per minute.

Initially a knowledge of Morse code was necessary for the preparation of the transmitter tape, but later keyboard perforators were devised that perforated all the holes corresponding to a character on depression of the appropriate key. Further improvements to the system included receiving reperforators that reproduced the original tape, facilitating retransmission, and the Creed printer which translated from the perforated tape to printed characters. The system required groups of operators at each end to keep it fully loaded

FIG. 7.—FIVE-UNIT CODE AND SEVEN-UNIT ERROR-DETECTING CODE

and was supplanted by more convenient multiplex systems. Nevertheless the system had a considerable life, even persisting on some radio circuits.

**Multiplex (Time Division).**—The alternative to a single high-speed communication is the division of the capability of the circuit among several operators, allocating a channel to each. This can be effected by allotting connection to the transmission line cyclically to each operator for a given period; e.g., one character (character interlacing) or one element (element interlacing). At the receiving end of the circuit the individual receiving devices are similarly connected in cyclic order so that they record the appropriate signals.

Systems on this principle had been proposed by Wheatstone and Moses G. Farmer. A certain amount of development was done by A. J. Meyer and P. B. Delaney, but J. M. E. Baudot produced the first successful system using a five-unit code and printing receivers. The principle is illustrated in fig. 8. The "clock" determining the period and sequence per channel and code element comprises a mechanical distributor in which an arm rotating with uniform speed connects the line sequentially to segments of a conducting ring that are connected to a battery through keys set to the code permutation.

After the transmission of one character, the permutation is changed in time for the next revolution, while the other channels are being dealt with. A similar distributor at the receiving station connects the receiving devices synchronously in similar sequence but with an appropriate time lag according to the signal propagation time. Special devices are used for maintaining accurate synchronism and correct phase between sending and receiving distributors. In the original system the code keys were operated directly, but in later usage perforated tape and automatic tape readers were introduced. Speeds of up to  $6 \times 40$  words per minute were achieved.

Systems based on the Baudot were used extensively on land lines until the late 1930s and are still used on submarine cables. They are also used on radiotelegraph links because synchronous operation affords a protective feature to transmission accuracy. Later developments in this field are leading to the obsolescence

FIG. 8.—DISTRIBUTOR SYSTEM (BAUDOT) FOR MULTIPLEX TRANSMISSION of the electromechanical distributor; electronic oscillators and pulse distributors, with no moving parts, provide the clock system for the sequential interconnection of the circuit elements.

**Multichannel Carrier Systems (Spectrum-Division Multiplex).**—Toward the end of the 19th century proposals were made to use tones of different frequency or pitch to carry telegraph code signals. Experimental systems by E. Gray and E. J. P. Mercadier proved unsatisfactory and it was not until further developments, particularly the thermionic valve, that practical systems were evolved toward the end of the 1920s. The principle of a carrier system is that, in place of a direct current, an alternating current is used to carry the code signals. This may be done by varying the amplitude of the carrier (e.g., switching on and off), changing the frequency (frequency modulation, FM) or changing the phase of the carrier (PM). Each of a number of different frequencies can carry a separate telegraph signal, the spacing of the frequencies depending upon the required speed of transmission. Each channel is controlled by an independent transmitter, and the outputs are connected to the common transmission line through electrical filters to prevent mutual interference. At the receiving station each channel is filtered out separately, and an amplifier-detector terminating in a relay reproduces a D.C. code signal for the operation of the receiving instrument.

The spacing of channels is standardized at 120 cycles per second (c.p.s.) for 66 words per minute teleprinter operation, and systems of 12, 18 and 24 channels are usual. In the United States 150- and 170-c.p.s. spacings are used and the speed is generally 60 words per minute, but later systems are capable of 100 words per minute; the number of channels varies up to 16. The range of frequencies is usually restricted to those of speech, and telephone circuits or carrier channels (on line or microwave radio) are used as the transmission path.

In Europe the majority of systems use amplitude modulation, while in the United States some of the original AM systems have been replaced by FM systems. The use of phase modulation involves some technical complexities and is not generally used.

Voice-frequency multichannel transmission by mid-20th century had become the most widely used method of providing main telegraph links and was extending into the field of intercontinental line communications. Multichannel systems are also applied to radiotelegraph routes. These are generally of the frequency-shift variety of modulation, which is less susceptible to the effects of noise and fading encountered on long-distance radio circuits.

## V. PRINTING TELEGRAPHS

The earliest printing telegraphs were worked on the step-by-step principle in which a type wheel with characters evenly spaced around its circumference is advanced by an electromagnet and ratchet one character for each current impulse received from the line. Trains of impulses caused the type head to rotate from one character to the next one; on cessation of the pulses a paper tape was brought into contact with the inked type at the printing position. This was a development from the Wheatstone ABC in

which the characters were only indicated on a dial. Such systems were used for many years for stock exchange quotation telegraphs. The major drawback was the liability of the type head to get "out of step" due to interfering currents in the line and means had to be provided to rotate the type wheel to a known position periodically.

An improvement on this system was produced by D. E. Hughes. The type head rotated continuously in synchronism with a distributor at the sending end, and operation of a piano-type keyboard caused a current impulse to be emitted at a point in the revolution corresponding to the chosen character. This, at the receiver, caused a paper strip to be brought momentarily in contact with the type wheel as the corresponding type passed the printing point. Speeds of up to 60 words per minute could be achieved by skilled operators, and this system persisted on some European circuits until the 1930s.

The Baudot multiplex system used printing receivers working with a five-unit code. Five levers, set in alternative positions by electromagnets, respond to the element signals and, when these coincide with a series of notches in a disk carried by the continuously rotating type-head shaft, a printing hammer automatically brings paper tape in contact with the inked type.

**Teleprinters.**—Until the 1920s the successful printing telegraph systems involved at some point in the system continuous synchronism of sending and receiving apparatus, which meant that a skilled setting-up procedure was involved before full-speed communication could take place and that a high degree of skill, including in some cases knowledge of the code, was demanded of operators. This restricted use of the most efficient methods to main lines. Methods were pursued which could be more universally applied and would demand less skilled control, thus enabling printing telegraphs to be used on local circuits where traffic is intermittent. To meet this requirement, telegraph machines (i.e., teleprinters or teletypewriters) were developed by E. E. Kleinschmidt and the Morkrum company in the United States, Cross and company in England and Siemens-Halske in Germany. From the mid-1940s other European countries produced similar machines. The teleprinter became the commonest telegraph instrument, and hundreds of thousands were in use in the second half of the 20th century.

The teleprinter comprises a keyboard similar to that of a typewriter and a printing mechanism that produces the received message either as a continuous line of type on a tape or in page form on a continuous roll of paper. The motive power is provided by an electric motor running at a controlled speed, but the mechanisms are coupled to it by clutches that are brought into operation automatically only when required.

The depression of a key of the keyboard causes each of a set of five bars to take up one of two positions according to the five-unit code permutation representing the character and also engages the clutch of the transmitting mechanism for the period of trans-

FIG. 9.—PERFORATED TAPES FOR AUTOMATIC TRANSMISSION AND SIGNAL CURRENT WAVE FORMS

mission of the individual character. A cam assembly permits a contact or contacts to be operated at discrete intervals in accordance with the setting of the permutation bars to form the code signal transmitted to line. The five-unit code signal is always preceded by a start element and succeeded by a minimum period of the rest condition ( $1-1\frac{1}{2}$  units in duration), hence this code is often termed a seven-unit start-stop code.

The received signals operate the teleprinter via an electromagnet. The first motion of the electromagnet armature engages the clutch of the mechanism, and at the mid-instants of the code elements the position of the armature is recorded by mechanical store elements, which are linked to the printing mechanism in one of several possible ways.

In one way, latches are selected to halt a rotating type head at the appropriate position; in others the positioning of slotted combination bars enable individual type bars, as in a typewriter, to be brought into action, or a rectangular type box is displaced according to the mechanical addition of the displacements of the storage elements. Since the receiver is started for the reception of each character, slight speed differences from the transmitter do not produce an accumulative phase error leading to malreception.

Teleprinters are capable of speeds of 60-100 words per minute and can be operated by competent typists. Where the utmost use of the line capability is desired, an automatic tape transmitter can be used in place of the keyboard. Receiving reperforators may be used, with or without printing, where retransmission over another circuit is necessary, to avoid rekeying the message.

## VI. LINE PLANT

Bare wires were used as line conductors as early as 1816. In that year, Francis Ronalds demonstrated a telegraph system that employed a bare wire covered with glass tubing impregnated with pitch and buried in the ground. However, for reasons of economy, the early commercial telegraphs were operated with bare wires supported overhead on poles. This open-wire pole-line construction was generally used thereafter, and even after the middle of the 20th century still constituted a large portion of outside telegraph plant. Cables, which are groups of insulated wire held together by a common cover or sheath, were introduced early in the century to a limited extent, and their utilization, both aerially suspended and underground, greatly increased thereafter. Open-wire pole-line construction and suspended aerial cable are commonly used in open country, but as telegraph lines approach congested areas, underground cables are generally used. Underground cable is also used almost exclusively for local distribution within a congested area.

**Overhead Lines.**—Poles used for supporting wires and cables are usually of wood, although steel and concrete poles are sometimes used. In open-wire construction the bare line wires are supported on insulators, usually of glass or rubber, mounted on pins set vertically in wooden crossarms. In general, bare copper wires are used, ordinarily about 0.114 in. in diameter, weighing 210 lb. per mile, or 0.104 in. in diameter, weighing 172 lb. per mile. Other sizes are employed to a limited extent, and wires of galvanized iron, bronze and other materials have been used with considerable success. Cables, when placed on poles, are supported by suspension strands, consisting of high-strength stranded wires. The weight of the cable to be supported determines the strength of suspension strands used, the heavier cables requiring strands having a strength exceeding 18,000 lb. Cables are fastened to the suspension strands by various means, and the suspension strands are fastened to the poles by small metal clamps.

Conductors in cables designed for telegraph service are of soft drawn copper varying in diameter from 0.036 in. to 0.102 in. Ordinarily, cable conductors are separated and insulated by paper wrapped spirally about them, although cables having rubber-insulated conductors are often used for short distances. The conductors are arranged in pairs which consist of two conductors twisted together or in quads consisting of two pairs twisted together, or four wires in spiral form. These pairs and quads are arranged compactly in layers. Paper insulated conductors are enclosed in a lead sheath, while rubber-covered con-

ductors may be enclosed in lead or a covering of heavy braid. The number of conductors provided in telegraph cables varies, the largest in common use in the early 1960s being 404 pairs. The outside diameter of this cable is  $2\frac{3}{8}$  in. and the weight  $7\frac{1}{2}$  lb. per foot.

**Underground Construction.**—Where cables are placed underground within a city, some form of conduit with independent duct space for each cable is usually employed to permit the cables to be readily installed and removed. The ducts are usually of hollow tile, creosoted wood or fibre. Iron pipe may be used in special situations. All ducts are three inches or more in diameter, and the conduit is buried at least two feet deep. As the length of cable which can be pulled through a duct is limited, splicing chambers or manholes are provided at intervals of about 500 ft. These manholes are at least 3 ft. wide, 5 ft. long and  $4\frac{1}{2}$  ft. deep, and in many cases considerably larger sizes are required. They are usually constructed of brick or concrete with a removable cover.

Cable is pulled into conduits one length at a time, and the ends are spliced together. In splicing paper-insulated cables, a foot or more of sheath is removed from the end and a few inches of the insulation is removed from the conductors. Conductors are then joined by twisting, soldering or other means, and the joints are insulated with small paper or impregnated cotton tubes. After all conductors are joined, the splice is wrapped with strips of muslin and a lead sleeve slipped over it. This sleeve is held at each end to the cable sheath by means of wiped soldered joints.

Where cables are laid underground in open country, it is feasible to bury such cables directly in the ground without conduit protection. Large machines prepare a trench, lay the cable and cover the trench in a single operation.

**Submarine Cable.**—In submarine cable the conductor is made of copper, stranded or having a central wire surrounded by strips wound spirally. Over this is molded the insulation. Formerly gutta percha was almost universally employed for the insulator, but deproteinized rubber, both natural and synthetic, later competed successfully with gutta percha, while polyethylene bid fair to supplant both of them. Continuous inductance loading in the form of a thin ribbon or thread of highly permeable nickel-iron alloy wound around the conductor greatly increased the speed at which the later cables could be worked. To protect the insulation at depths where marine borers are found a brass tape is wound around it. Next comes a cushion of jute yarns upon which the spirally wound armour, or sheathing wires, rests. In the deeper portions of the ocean galvanized high-tensile steel wires are used, sometimes individually covered by tarred cotton tape or braid. As the depth decreases these are replaced by galvanized wrought-iron wires of larger size, and the armour gradually is increased in size and weight until, near the shore, a double layer is used. The added protection is necessary to prevent damage from anchors, trawler fishing gear, chafing against rocks and, in northern latitudes, ice. An outer double wrapping of tarred jute yarn or jute tape steeped in a compound of tar and pitch further preserves the armour from corrosion. The outside diameter of the ordinary deep-sea type of cable is about one inch, and the weight in air about two tons per nautical mile. The shore-end types run as large as  $3\frac{1}{2}$  in. in diameter and weigh as much as 30 tons per nautical mile.

## VII. TRANSMISSION THEORY

In a direct-current telegraph circuit the transmitted signal can be considered as a sequence of similar rectangular pulses of potential applied at time intervals that are multiples of the duration of the shortest code element, as in the example in fig. 10(A). Analysis of the elementary pulse wave form into sine wave components by Fourier's method shows that it contains a band of frequencies ranging from zero to infinity; the relative magnitudes are indicated in fig. 10 (B). If the duration of the element pulse is  $T$  seconds ( $T$  might be 0.02 sec. in teleprinter operation), there will be no components at precisely  $\frac{1}{T}$ ,  $\frac{2}{T}$ ,  $\frac{3}{T}$ , c.p.s. When a particular pattern of pulses of duration  $nT$  seconds is continuously repeated, the components become concentrated at fre-

quencies that are multiples of  $\frac{1}{nT}$ , but the relative magnitudes are still bounded by the fundamental curve. As an example, if the signal is a repeated train of Morse dots,  $n = 2$  and the component frequencies are  $\frac{1}{2T}$ ,  $\frac{3}{2T}$ ,  $\frac{5}{2T}$ , . . . c.p.s.; i.e., the fundamental plus the odd harmonics of the dot frequency (fig. 10[C]).

FIG. 10.—EXAMPLES OF TELEGRAPH TRANSMISSION WAVE FORMS (see TEXT). ( $E$  = VOLTAGE)

This may be more readily appreciated by reference to fig. 10(D), which illustrates how the combination of the first three components begins to approximate the rectangular wave form.

To reproduce the signal wave form completely at the receiver, it would be necessary for the telegraph line to transmit all the frequency components without change of relative amplitude and phase, but in practice this is unnecessary. The energy conveying the essential message is concentrated in the lower part of the frequency spectrum, and the higher-frequency components may be discarded without destroying the message. Excellent operation can be obtained when the circuit reduces frequencies corresponding to  $\frac{9}{27}$  c.p.s. to one-half of their original amplitude relative to the fundamental component and the response at frequencies of  $\frac{3}{27}$  c.p.s. is negligible. However, on local lines where the transmission capability is more than adequate, it is usual to transmit a frequency range including  $\frac{3}{27}$  c.p.s., to permit less critical adjustment of apparatus.

In carrier transmission, there is a similar distribution of signal energy with respect to frequency in side bands symmetrically located about the carrier frequency, the lower side band being a mirror image of the upper one. Hence the frequency band width required is double that for direct-current transmission.

The energy of the signal is dissipated in transmission to an extent dependent on the resistance, capacitance, inductance and leakage of the line. The effects of capacitance and inductance increase with frequency but have some opposing characteristics. The inherent characteristics of telegraph cables are such that the resistance and capacitance preponderate, so by artificially increasing the inductance (i.e., "loading" the cable), by the insertion of inductor coils at uniform distances or by wrapping the conductor with magnetic material, the dissipation of the higher frequencies can be reduced and a higher speed of operation obtained. Even with this, the relative magnitudes of the various frequency components have to be modified to the correct proportions by inserting at the sending or receiving end (or both) of the line correcting devices or equalizers with frequency responses that compensate for those of the line.

The transmission path may be subject to interfering currents from various sources; e.g., induction from other telegraph systems, power supply systems, stray currents from traction systems or varying earth potentials due to changes in the earth field. The magnitude of interfering currents limits the speed of operation on a long cable because the higher frequencies required are severely reduced in magnitude and the signals become too deformed to be interpreted correctly.

**Telegraph Distortion.**—The perfect telegraph signal changes its condition according to the code at predetermined intervals of time. In the course of transmission it is restricted in frequency range, either purposely to prevent the higher frequencies from interfering with other channels in a multichannel system or incidentally by the line characteristics, so that the transitions from one condition to the other are not abrupt but occur in a finite time. The receiving instrument or relay is operated from one condition to the other when the received current attains certain values. If there are no interfering currents, the transmitting path is conveying the currents of various frequencies in the correct relationships and the relay is adjusted to the correct operating values, the signal will be perfectly reproduced (assuming a perfect transmitter) with the transitions taking place at the prescribed intervals. But if interference is present these currents will increase, or decrease, the signal received and the relay operating currents will be attained at other instants. Similar displacements in time of the relay operations will ensue if the relay is maladjusted or the line is incapable of transmitting the required range of frequencies in their proper relationship. If the telegraph distortion (time aberration of the signal) is too great, the margin (maximum acceptable distortion) of the receiver will be exceeded and confusion with other code signals will ensue.

## VIII. TELEGRAPH SWITCHING

Communication between a large number of stations requires either direct lines from each to every other one or means of transferring messages from one line to another at central points. Stations can be grouped around different centres and distant traffic concentrated to use intercentre lines at higher efficiency. In the early days of telegraphy, the only means of handling messages between widely separated points was to record them at intermediate points and retransmit them on the next stage of the route. About the beginning of the 20th century exchanges were brought into use in large cities for the manual interconnection by means of switchboards of local lines using hand-speed Morse, but the diversity of methods and speeds used on long-distance lines dictated the continuance of the employment of operators at long-distance centres, which persisted at places dealing with international traffic to the late 1950s.

The successful introduction of telegraph exchanges awaited the development of a standardized telegraph machine and cheaper telegraph circuits, which eventuated as the teleprinter and multichannel carrier systems.

**Teleprinter Manual Switching.**—In the early 1930s a few European countries introduced subscriber exchange service, Telex, for teleprinters, using single-channel voice-frequency signaling over the public telephone networks. In the second part of the decade this service was extended internationally. During World War II the development of teleprinter communication proceeded rapidly on both sides; large manually switched networks were put into operation using separate telegraph circuits comprising multichannel systems on main routes and direct-current signaling on local circuits. In the United States the extensive exchange system (TWX) was based on a line system using derived direct-current circuits and multichannel carrier.

The switchboard closely resembles a telephone manual switchboard in which lines terminate in jacks (sockets) that are interconnected as desired by flexible conductor cords terminating in plugs. The operator, of course, communicates with the subscribers by teleprinter.

**Teleprinter Automatic Switching.**—The desire for further reduction of human intervention in telegraphs led to automatic switching on principles similar to those for telephony. Systems

were designed during the mid-1930s and in fact introduced to a limited extent in Germany before World War II. Introduction elsewhere in Europe was delayed until the late 1940s and '50s. In some countries the operator is provided with a dial, like that of an automatic telephone, for setting up a connection; in others the called number is sent from the keyboard, and apparatus at the exchange converts the signals to pulses for operating the switches. Special signals are sent back for indications of "engaged," "line out of order," "number unobtainable," etc., to be printed. On receipt of a call the teleprinter is automatically started and sends its own number automatically to confirm the connection to the caller.

**Reperforator Switching.**—The systems of switching so far mentioned provide both-way communication (but not necessarily simultaneously) by direct line connection between two stations. However, flexibility in message handling can be achieved by semi-automatic or automatic means in which the message is received as perforated tape in the exchange and then retransmitted over an appropriate outgoing line to the recipient or the next switching centre en route. The idea of tape relay systems led in the late 1930s to the development of the printing reperforator by which the message is simultaneously typed on the tape as it is perforated. In the first systems, operators read the address from the tape which was torn off on completion of the message and transferred it to the appropriate position in the office, where it was sent onward with an automatic transmitter. This system was further developed so that the receiving operator could place the message tape in one of an adjacent group of autotransmitters and connect that automatically to the required outgoing line by pressing the appropriate one of a group of buttons controlling relay switching apparatus. By the mid-1950s fully automatic tape relay was achieved. In this, the originating operator sends route code letters at the head of the message. The code letters are sensed automatically following reperforation and interpreted by a director that automatically sets up connections through the exchange and causes the message to be retransmitted at high speed to a reperforator and associated retransmitter, from where it is sent out on the next section of its route. If lines are busy at any stage in the process, the message is kept stored in the perforated tape.

**Applications.**—In the early 1960s the use of switching systems was extensive and extending rapidly to reduce the labour costs of human handling. Europe generally appeared to favour the line-switching technique for the public services, both Telex and ordinary telegrams, and automation proceeded. Private networks operated by public utilities and business concerns for communication between head and branch offices and factories, etc., employed various of the systems described.

United States practice followed two distinct patterns. The subscriber service (TWX) was, necessarily, a line-switching system, but the public telegraph service (Western Union Telegraph Company) developed on a message-switching basis, due largely to the economic relationship between costs of station apparatus and transmission channels where great interurban distances are involved. There were also many large private networks.

Military organizations of nations with overseas bases operated world-wide systems in which message switching was employed. Trunk circuits were carried by cable and radio.

## IX. SUBMARINE TELEGRAPHY

Except for a few river and harbour cables, the first submarine cable was that laid in 1850 between England and France. It was broken shortly after communication had been established but was successfully followed the next year by another, between Dover and Calais. The first transatlantic attempt in 1857 was a failure when the cable broke at 2,000 fathoms' depth during laying and could not be recovered. However, the Atlantic was spanned in 1858 between Ireland and Newfoundland. After a few weeks the cable's insulation failed, and it had to be abandoned. It was 1866 before the first permanently successful transatlantic cable was laid. In the same year another cable, partially laid in 1865, was also completed. These two, with which the U.S. financier Cyrus Field and the British scientist Lord Kelvin were closely associated, were

the only transatlantic cables until 1869, when the French laid a cable. In the following 60 years, the earth-encircling telegraph cable network became fully established, and no new long-distance routes were established afterward.

The principle of inductive loading proposed by Oliver Heaviside in 1887 was applied to some short cables at the turn of the century, but it was not until the 1920s, when improved magnetic alloys became available, that it could be applied economically to very long cables. Even so, only a few long telegraph cables (across the Atlantic and Pacific oceans) are of this type. Advances in utilization were chiefly due to improvements in the cable apparatus.

**Sending.**—Originally, except for the attempt to use printing telegraphs on the first cross-channel cable, hand-speed Morse operation was used. Due to the lack of knowledge about methods of equalizing the transmission of the various frequency components of signals in the early days, the long and short elements of the code suffered appreciable distortion, and the cable-code method which uses equal length pulses of opposite polarity for dots and dashes was used. It was also found advantageous to apply short reversed periods of opposite polarity following each code element ("curbing"). Except for relatively short cables, it was not found satisfactory to use five-unit code until it was introduced by the U.S. companies on transatlantic loaded cables. Other operators maintained the use of cable code chiefly because of large investment in extensive systems of chains of interconnected cables.

Hand sending with the double key in cable code was superseded by the automatic transmitter modified from the Wheatstone machine by two French engineers, Belz and Brahic, in 1879, which used a perforated tape. Later, as techniques for reception improved and higher speeds became possible, multiplex operation was introduced.

**Receiving.**—Due to the characteristics of long submarine cables and the requirement to extract the greatest speed from an expensive channel of communication, the received currents are very feeble, often effectively only of the order of ten microamperes. This necessitates much more sensitive apparatus than that employed on land lines. The earliest specialized instrument was the mirror galvanometer of W. Thomson (later Lord Kelvin) by which the signals were read as deflections of a reflected spot of light on a scale; this was used on the first Atlantic cable. In 1867 Thomson produced the siphon recorder, in which an ink siphon is harnessed to the moving coil of the galvanometer so that the signals are recorded as an undulating line on paper tape. With the development of sensitive relays more robust recording instruments could be employed and receiving reperforators appeared about 1900. This greatly facilitated retransmission at intermediate stations. In the early 1920s the invention of the Creed Morse printer provided the next step of translation from the perforated tape. About ten years later a direct printer which could cope with the various-length cable-code signals completed the development of cable-code operation.

The higher speeds made possible by the loaded cable led to the use of five-unit code on certain routes to facilitate repetition of signals from land-line multiplex systems. The higher capability of the cable was difficult to realize reliably with the existing electromagnetic relays which decrease in sensitivity as they are adjusted for higher speed, and so thermionic valve terminal amplifiers were introduced to amplify the signals for use with more robust high-speed relays to feed the multiplex apparatus.

**Transmission and Repeaters.**—Simplex operation was used in the early days of submarine cables, but the desirability of duplexing was immediately felt. Early attempts were not very successful, because the weak received signals made it imperative to achieve accurate and stable artificial lines for balancing the cable, since the residual unbalance introduced interference from the sent signals at the same end. Improvements in the manufacture and adjustment of artificial cables made duplex operation usual on unloaded cables, but no generally satisfactory means of producing a balance for loaded cables was found. However, one special cable, laid in 1928 between Nova Scotia and the Azores, had graded load-

ing that tapered to zero at the ends and was successfully duplexed.

The possible speed of operation of a given type of cable terminating at a particular station will be inversely proportional to the square of its length, so where convenient it is desirable to split long routes into sections, locating repeater stations on islands on transoceanic routes where the signals can be completely regenerated. The ultimate limit in speed is determined by the interference induced by natural phenomena, such as changes in the magnetic and electric fields of the earth and electric storms. These effects are manifested in shallow water near the shore, so if the signal can be amplified before it reaches this area, it can be raised above the interference level and faster operation obtained. The technique of the submerged telegraph repeater was first employed by the Western Union Telegraph company in 1950. The repeater consisted of a valve amplifier with equalizing networks, contained in a watertight steel case, the necessary power for its operation being supplied from the shore via the cable. Such repeaters may be located 60–300 mi. from shore at depths of 250–1,250 fathoms. Such a repeated cable can be operated only in the simplex fashion, but the speed may be increased three- or four-fold over unrepeaters duplex. This method is best employed on routes where there are at least two cables to provide both-way communication, but repeaters can be inserted in both ends and be switched in or out of circuit from the shore to reverse the direction of working.

Submerged telegraph repeaters have been applied to many of the transatlantic telegraph cables by U.S. companies and to a few in the British commonwealth cable system.

Typical speeds of operation of long-distance unloaded cables range from 250 to 600 characters per minute duplex. Loaded cables about 2,000 mi. long are capable of 2,500 characters per minute simplex, and repeated unloaded cables attain similar speeds.

## X. RADIO

Radiotelegraphy is essentially carrier telegraphy at relatively high frequency. The radio carrier may be directly modulated by the telegraph signal in any of the usual modes (i.e., amplitude or frequency) or by a subcarrier system of one or more channels (i.e., the telegraph signals may be borne over a line to the radio transmitting station by a voice-frequency carrier that is then sent by a radiotelephony transmitter). Radio propagation over long distances is subject to severe disturbances that cause the signal to fade and introduce interference by atmospheric noise, which results in distortion and sometimes mutilation of the signal. To minimize these effects, diversity reception may be employed. Diversity can be of several forms: time diversity in which the message is repeated twice and the most likely version of the message accepted in the case of disagreement; space diversity in which two receiving aërials separated by a considerable distance feed a special receiver that selects the stronger signal; or frequency diversity in which the telegraph signal is sent simultaneously on two different frequencies.

Teleprinter transmission can be more seriously impaired than synchronous transmission, because if the start or stop elements of character signals are incorrectly received, the mechanism is likely to become out of step and successive characters to be incorrectly printed. Therefore, on regular fixed traffic routes, synchronous time-division multiplex is often employed and as a further protection a seven-unit error-detecting code may be adopted. When a return channel is available a system of automatic error-correction devised by Van Duuren is used. In this, the detection of an error causes a special signal to be sent back to the transmitting office to request the automatic repetition of the previous three characters of the message, which are automatically stored in the apparatus; meanwhile, the output of the receiving apparatus is blocked until the originally faulty signal has been received again. If this is then apparently correct, through transmission is resumed; if not, the automatic repetition cycle is repeated. In practice, the error rate in the printed message may be reduced by a factor in the order of 100. Such systems can be connected in teleprinter networks; the teleprinter signal is re-

ceived at the sending terminal station on a reperforator, and the tape from this is accepted by the multiplex apparatus, which automatically translates it into the special seven-unit code. At the receiving end of the multiplex the signals, after being checked for conformity, are automatically translated back into teleprinter code signals.

In some countries, particularly where interurban distances are great and the terrain rugged, microwave radio-relay systems are being introduced as more economical than long-distance carrier telephone cable, and channels in such systems can be used to bear multichannel telegraph systems. See also references under "Telegraph" in the Index.

**TELEKI, PÁL**, COUNT (1879–1941). Hungarian scholar and prime minister, was born in Budapest on Nov. 1, 1879, of a famous Transylvanian family. He entered Parliament as early as 1905 but found time to travel widely and to acquire international distinction in his favourite field, geography. He was premier from June 19, 1920, to April 14, 1921, but then withdrew from party politics in which he never greatly believed, holding the true functions of government to be educative and moral. He held a chair of geography at Budapest University and was also head of the Cartographic Institute and president of the Boy Scouts Association. He returned to office as minister of education on May 14, 1938, and became premier again on Feb. 15, 1939. Passionately convinced of the justice of Hungary's claim for a revision of the Treaty of Trianon (q.v.), he nevertheless struggled to avoid any dependence on Germany. During World War II he concluded a treaty of eternal friendship with Yugoslavia (December 1940). After the Yugoslav coup d'état of March 1941, however, Germany demanded Hungary's help against Yugoslavia, while Great Britain threatened dire consequences if Hungary gave it; and in the night of April 2–3, 1941, Teleki took his own life.

See C. A. Macartney, *October Fifteenth*, 2nd ed. (1961).

(C. A. M.)

**TELEMANN, GEORG PHILIPP** (1681–1767), the most highly regarded German composer of his time, was born at Magdeburg on March 14, 1681. Self-taught as a musician, he entered the University of Leipzig in 1701, intending to study law. He soon abandoned his studies for a musical career, however. He founded the Collegium Musicum (students' orchestra), undertook the refection of the Leipzig Opera, and, in 1704, was appointed organist at the Neue Kirche. In 1705 he left Leipzig, and, after some years as court composer at Sorau and Eisenach and as musical director at

Frankfurt-am-Main, he finally settled in Hamburg in 1721. In 1722 he was offered the post of organist at the Thomaskirche, Leipzig. He declined the position, which was then given to J. S. Bach. In 1737-38 he traveled for eight months in France.

As a composer Telemann was amazingly productive. In Hamburg he provided five churches with music; he conducted the opera and gave frequent concerts with the Hamburg Collegium Musicum (which he had formed). In addition to these activities, he regularly supplied music for several courts and for the city of Frankfurt. Within the space of 15 years no less than 44 of his works were published—some engraved by himself—among them several complete sets of cantatas for the church year, the large instrumental collection *Musique de Table*, and the first music periodical, *Der Getreue Music-Meister* (which alone contains 70 of his compositions).

Telemann was on friendly terms with J. S. Bach, to whose son Carl Philipp Emanuel he became godfather; Handel sent him rare plants for his garden; and Johann Mattheson was enthusiastic in his praise. Both Bach and Handel copied and arranged several of his works for their own use. He was twice married and had eight sons and two daughters, but of his family only one grandson, Georg Michael Telemann, became a musician. Telemann died in Hamburg on June 25, 1767.

In his lifetime Telemann was most admired for his church compositions. These vary from small cantatas, suitable for domestic use or for use in churches with limited means, to large-scale works for soloists, chorus, and orchestra.

Telemann's secular vocal music also has a wide range, from simple strophic songs to the dramatic cantata *Ino*, written at the age of 84. Of his operas the comic ones were the most successful, particularly *Pimpinone*, based on the same plot as Pergolesi's *La serva padrona*, which it preceded by eight years. His orchestral works consist of suites (called *ouvertures*), *concerti grossi*, and concertos. His chamber works are remarkable not only for their quantity but for the great variety of instrumental combinations and the expert writing for each instrument. Representative of his instrumental output is the collection *Musique de Table*, containing orchestral suites, concertos, and chamber music.

Telemann's compositions combine the principal styles and forms of his time—Italian, French, and German, with some excursions into Polish and English territory. His music is notable for its expressive melodies, surprising harmonies, buoyant rhythms, masterly instrumentation, its wit, and its variety.

An edition comprising a selection of Telemann's works was published by Bärenreiter (1953- ). (W. G. BE.)

**TELEMARK**, a fylke (county) of southern Norway. Area 5,919 sq.mi. (15,329 sq.km.). Pop. (1960) 146,634. From the coast of the Skagerrak it extends 112 mi. (180 km.) northwestward, covering uplands and mountains carved by many branched valleys: Gausta (6,178 ft.; 1,883 m.), near Rjukan, is the highest point. Numerous lakes include Tinnsjø, Møsvatnet, Totak, Fyresvatn, Nisser, Bandak, Heddalsvatnet, and Norsjø. Norsjø is connected by canals with Bandak and Heddalsvatnet, giving access from the ports of Skien and Porsgrunn to Dalen and Notodden. The county is crossed in the north by a highway between eastern and western Norway, and in the south by the Oslo-Stavanger railway, with branches to the coastal towns of Brevik and Kragerø. Huge waterfalls at Rjukan and Notodden provide power for electrochemical works. The power potential of the Tokke River beyond Lake Bandak was being developed during the 1960s to provide an important addition to the public supply of southeastern Norway. The county town, Skien (pop. [1960] 15,251), one of the oldest towns in Norway and the seat of a court of appeal, is an important centre of the pulp and paper industry. Porsgrunn (10,423) is known for its porcelain factory. Kragerø (9,686) is a picturesque summer resort and yachting centre. (L. H. HG.)

**TELEMETRY** is that branch of electronic engineering concerned with the measurement of physical signals at a remote location. It encompasses measurement of the variable at the source, separation of the relevant information, and its transmission to a desired location where it is displayed.

The most advanced technical developments of telemetry are utilized in the space program. An unmanned orbiting vehicle is the site of measurements of surface temperatures, magnetic fields, ambient radiation intensity, and other variables necessary in the scientific investigation of space and the development of improved vehicles. In a manned vehicle, additional instrumentation monitors such signals as the astronaut's pulse rate, blood pressure, and respiration rate. Success of the mission and control during the flight require that the results of these measurements be transmitted as frequently as possible to earth receiving stations. (See also SPACE EXPLORATION.)

Telemetry is also utilized in the control of gas flow through long-distance pipelines. Telemetry equipment measures pressure and flow along the line and transmits the information to control stations where pumps and valves are adjusted to ensure constant pressure for all users. Other applications include systems for the automated computer control of industrial processes (e.g., factories) and equipment for basic research in biology, particularly for studies involving observation of physiological signals from animals inaccessible in normal activities.

The telemetry system ordinarily includes: (1) measurement devices; (2) data-processing equipment at or near the point of measurement; (3) electronic communication equipment to transmit the information (e.g., by wire or radio) to the desired site; (4) data-processing equipment at the receiving station; and (5) display devices (cathode-ray tubes, loudspeakers, or tape recorders). Items (2) and (4) are the system elements unique to telemetry.

Efficient design of the telemetry system commonly requires that the data-processing equipment collect information from many (e.g., 30) measurement devices and combine the data in such a way that a single electrical signal can be transmitted that will convey the measured variables simultaneously. The desired economy of communication equipment and channel capacity is achieved by a combination of time and frequency multiplexing—the distinguishing characteristic of electronic telemetry systems.

Time multiplexing is the process of time sharing among distinct signals. Any physical signal can be decomposed into a sum of sinusoidal signals of various frequencies (e.g., speech consists primarily of sinusoidal signals of frequencies from 100 to 4,000 cps [cycles per second]). The fundamental sampling theorem of communication theory states that all the information in a signal can be represented by a sequence of samples of the signal, with the samples taken at a rate at least twice the maximum frequency of the signal (e.g., speech can be represented by 8,000 samples per second, even though each sample may be only one-millionth of a second in duration).

Thus, time multiplexing is accomplished by iteratively sampling each of the set of signals. If the 20 signals A, B, C, . . . , T are to be transmitted and each must be sampled ten times per second, the data-processing equipment samples signal A for  $\frac{1}{200}$  sec., then B for the next  $\frac{1}{200}$  sec., and so forth through the sequence. After  $\frac{20}{200}$  sec. ( $\frac{1}{10}$  sec.), the second sample of signal A is taken. The single, composite signal to be transmitted to the receiving station then includes the information on all 20 physical measurements. The time sampling can be accomplished by electronic circuitry automatically switching among the 20 signals or by a rotating electric switch that connects the output electrical circuit successively to each of the measurement instruments for  $\frac{1}{200}$  sec.

Frequency multiplexing is accomplished by simultaneously transmitting over a common path signals from several sources, each signal being assigned a distinctive reference frequency or band of frequencies. For example, long-distance telephone equipment (underground cable or microwave relay) permits transmission of signals from 100 cps to more than  $10^6$  cps; if separate speech signals are modulated (or shifted in frequency), 250 signals each of 4,000 cps bandwidth can be transmitted simultaneously over one system. The modulation process is accomplished with electronic equipment analogous to that utilized in commercial radio and television broadcasting (see BROADCASTING).

The transmitted signals are received by electronic equipment where demodulation devices separate the individual signals for operating the distinct display and recording instruments or provide

input data for a digital computer used to interpret the measured data. (J. G. TL.)

**TELEOLOGY** means explanation by reference to some purpose or end (Greek *telos*, "end"; *teleios*, "complete"); also described as final causation, in contrast with explanation by reference to efficient causes only. Human conduct, insofar as it is considered rational, is generally explained with reference to ends pursued or alleged to be pursued; and human thought tends to explain the behaviour of other things in nature on this analogy, either as of themselves pursuing ends, or as designed to fulfil a purpose devised by a Mind external to nature. The most celebrated account of final causation was given by Aristotle when he laid down that for a full explanation of anything it was necessary to take account not only of the "material," the "formal," and the "efficient" causes, but also of the purpose for which the thing existed or was produced, namely its "final" cause.

With the rise of modern science in the 16th and 17th centuries, interest was directed to mechanistic explanations of natural phenomena with reference to efficient causes; if teleological explanations were used they took the form, not (as in Aristotelian teleology) of saying that things develop toward the realization of ends internal to their own natures, but of looking even on biological organisms as machines ingeniously devised by an Intelligent Being. William Paley gave classical expression to this kind of teleology (*Natural Theology, or Evidences of the Existence and Attributes of the Deity Collected From the Appearance of Nature*, London, 1802).

In the 19th century controversy centred on whether the phenomena of growth, regeneration, and reproduction characteristic of living organisms could be explained in purely mechanistic terms. The "vitalism" of Hans Driesch (1867–1941), according to which some entelechy (*q.v.*) must be postulated in an organism, found little support after his death. There remains, however, the question whether biological processes can be explained purely in physicochemical terms ("mechanistic" explanation), or whether the problems of structure, function, and organization necessitate some kind of teleology.

See C. D. Broad, *The Mind and Its Place in Nature* (1925); J. Woodger, *Biological Principles* (1929). (D. M. E.)

**TELEOST**, any typically bony fish belonging to the group Teleostei. In the classification issued in 1846 by Johannes Müller, the geologically modern bony fishes were arranged in three subclasses, Dipneusti, Ganoidei, and Teleostei, the last including the great majority of the fishes, all those with a homocercal tail fin. Subsequent work, especially on fossil fishes, has shown that the ganoids are not a natural group, some being related to very primitive fishes, others, namely the Holostei, which include the recent bowfin and gars, *Amia calva* and *Lepidosteus*, approaching the teleosts.

The extinct Pholidophoridae and Oligopleuridae are exactly intermediate in structure between the Holostei and Teleostei, and have been included by some authorities in the one group, by others in the other. This led C. T. Regan to combine the Holostei and Teleostei to form one subclass, termed Neopterygii. See FISH.

**TELEPHONE.** The term telephone (from the Greek roots, *tele*, "far," and *phoné*, "sound") was first used to describe any apparatus for conveying sounds to a distant point. Specifically, the word was applied as early as 1796 to a megaphone, and not long afterward to a speaking tube. Subsequently the name string telephone was given to the device invented long before by Robert Hooke (1667), in which vibrations in a diaphragm caused by voice or sound waves are transmitted mechanically along a string or wire to a similar diaphragm which reproduces the sound. Still later, devices employing electric currents to reproduce at a distance the mere pitch of musical sounds were called telephones. Nowadays, however, this name is assigned almost exclusively to apparatus for reproducing articulate speech and other sounds at a distance through the medium of electric waves. The term telephony covers the entire art and practice of electrical speech transmission, including the many systems, accessories and operating methods used for this purpose.

## I. INVENTION

Like most inventions, the telephone drew heavily upon previous work and had scarcely appeared before notable improvements were made. Among the pioneer contributors in this field, the most outstanding was Alexander Graham Bell, who invented, and patented

BY COURTESY OF BELL TELEPHONE LABORATORIES, INC

FIG. 1.—TRANSMITTER OF JOHANN PHILIPP REIS, 1861 OR 1862

in 1876, the first telephone capable of practical use. As early as 1874 he had conceived the correct principle of telephone transmission, which he later stated as follows: "If I could make a current of electricity vary in intensity precisely as the air varies in density during the production of sound, I should be able to transmit speech telegraphically."

This conception of an undulatory current corresponding to a speech wave formed the foundation for the entire telephonic art. Earlier workers, notably C. G. Page in the United States (1837) and Charles Bourseul in France (1854), had devised methods employing the make-and-break principle of the telegraph for transmitting the pitch of sounds, but not articulate speech, to a distant point.

J. P. Reis came closer. Working at Frankfurt, Ger., in 1860 and subsequent years, he devised an apparatus using at the transmitting end a diaphragm structure something like that of the human ear to control an electric current (fig. 1). At the other end of the circuit this produced audible tones by controlling the magnetization of a needle whose changes of length, in accordance with the magnetostrictive effect discovered by Page, vibrated a sounding board. Later, an electromagnet was substituted for the needle. Reis's mechanism, like others before and after, included the im-

important feature of deriving the electrical power for transmitting sound by making the sound power control the current from a battery.

Reis had some comprehension of the requirement for electrical transmission of speech, for he noted in his memoir on telephony the need "to set up vibrations whose curves are like those of any given tone or combination of tones" (S. P. Thompson translation). Though his apparatus served primarily to reproduce tones by the make-and-break scheme, he did, by extremely delicate adjustment, succeed in reproducing articulate sounds quite imperfectly. Reis seems not to have realized, however, that this success resulted because his apparatus could, over a very narrow range of speech volume, operate on the principle of changing an electric current in accordance with the voice wave by varying a loose contact, in this case a spring contact between platinum electrodes. His understanding of his own apparatus is indicated by his statement that "each sound vibration effects an opening and a closing of the current." About 20 years later, the German patent office after careful investigation decided that Reis's instrument was not a "speaking telephone."

In the following years attempts were made by other workers (e.g., the Italians A. Meucci and F. Manzetti) but without full realization of the requirements for articulate speech.

Bell's approach was different. In the summer of 1874 the idea of the "electric speaking telephone" became complete in his mind. He described to his father a form of apparatus consisting of a strip of iron attached to a membrane which, when actuated by the voice, would vibrate in front of an electromagnet, thus inducing an undulatory electric current theoretically capable of transmitting speech. At the receiving end a similar device could be used in reverse to reproduce the voice. But Bell doubted that the current generated by the voice would be strong enough to be useful, and for almost a year he made no attempt to construct the apparatus. On June 2, 1875, while working in Boston on multiplex telegraph apparatus, Bell heard over an electric wire a sound corresponding to the twang of a steel spring at the other end. Recognizing this as a manifestation of the undulatory current principle, he gave his assistant, Thomas A. Watson, instructions for embodying it in a model (fig. 2) of a telephone. The transmitter and receiver were of the electromagnetic type described a year before, and

voice-actuated diaphragm varied the electrical resistance, and hence the current, by changing the depth of immersion of a rod in water. Bell in his application mentioned the possibility of a similar liquid transmitter, and later used it for his historic summons to Watson. The variable-resistance principle, which subsequently, in the form of a variable carbon contact, proved vital to telephone transmission, makes it possible to obtain an electric wave which is an amplified copy of the sound wave. Like Bell's receiver, Gray's was of the electromagnetic type, similar to one he had patented in Great Britain in July 1874 and in the U.S. in July 1875.

In view of Bell's prior filing of a patent application, the patent for the telephone was issued to him on March 7, 1876. Gray's status as to the invention of the telephone is best set forth in his own words, written to Bell on March 5, 1877: "I do not claim even the credit of inventing it." The claims of Gray, Daniel Drawbaugh and others were subsequently threshed out in prolonged litigation, involving about 600 separate suits, which finally resulted in Bell's patent's being upheld in a divided vote by the supreme court of the United States.

Bell's first transmitter employing electromagnetic induction, while valid enough in theory, delivered such feeble electrical currents as to be inadequate for general application. The liquid transmitter afforded considerable improvement, but this too had drawbacks. The final essential element for a satisfactory working telephone was the variable-contact carbon transmitter, due in large measure to Thomas A. Edison, as discussed below.

## II. INTRODUCTION AND GROWTH

**1. United States.**—The development of the telephone business in the United States was undertaken by a group of Bell's backers, under the leadership of Thomas Sanders and Gardiner G. Hubbard. They began by renting or lending telephones in pairs to individuals for local communication. The instruments were extremely crude. Connection between them was made by a circuit consisting of a single iron wire with ground return; transmission, which was uncertain and poor at best, was possible for only a few miles. Initially there were no switchboards to interconnect a number of

between was a circuit which included an electric battery. This apparatus transmitted speech sounds the next day, June 1. Bell filed his application for a U.S. patent on Feb. 14, 1876 (fig. 3). Further experiments produced an instrument which on March 10, 1876, transmitted the first complete sentence: "Mr. Watson, come here; I want you." A few hours after Bell filed his application for patent, Elisha Gray filed a caveat (i.e., a notice of intent to perfect his ideas and file a patent application within three months) for an electric telephone. Gray described a "liquid transmitter," somewhat similar to one patented by Thomas A. Edison for telegraphy in 1873. In Gray's transmitter a

users. These came into being in 1877 and 1878.

It was on March 25, 1878, that Bell made a bold prediction that became a charter for the founders of the telephone business:

It is conceivable that cables of telephone wires could be laid underground, or suspended overhead, communicating by branch wires with private dwellings, country houses, shops, manufactories, etc., uniting them through the main cable with a central office where the wires could be connected as desired, establishing direct communication between any two places in the city. Such a plan as this, though impracticable at the present moment, will, I firmly believe, be the outcome of the introduction of the telephone to the public. Not only so, but I believe, in the future, wires will unite the head offices of the Telephone Company in different cities, and a man in one part of the country may communicate by word of mouth with another in a distant place.

I am aware that such ideas may appear to you Utopian. . . . Believing, however, as I do that such a scheme will be the ultimate result of the telephone to the public, I will impress upon you all the advisability of keeping this end in view, that all present arrangements of the telephone may be eventually realized in this grand system. . . .

The owners of the telephone patent early incorporated their business, and funds were raised for its progressive development, under the leadership of Theodore N. Vail, who became general manager in 1878. It was recognized that telephone performance is a matter of mutual concern to users, and the practice was established of leasing telephones instead of selling them.

Within ten years after the issuance of the Bell patent, the organization of the Bell Telephone system had assumed something close to its present form. The local systems were gradually brought together into regional companies operating throughout a state or several states. The systems of these regional companies were linked together by long-distance circuits operated by the American Telephone and Telegraph company. This company, through ownership of stock in the regional companies, became the parent company of the Bell system.

The Western Electric company was acquired in 1882 as chief manufacturer and supplier for the Bell system, as well as to conduct research and development. In 1925 the Bell Telephone laboratories was organized to take over the expanding research and development activities for the system. In the 1960s the American Telephone and Telegraph company had more than 2,400,000 stockholders, constituting the largest number of public owners for any one corporation in the world.

After the expiration of the basic telephone patents, many independent telephone companies sprang up all over the country. Competition became so intense that in many localities there were two companies sharing the business. As this became an increasing source of inconvenience and expense to the public, the service was unified through acquisitions and mergers so as to leave a single company, either Bell or non-Bell, operating in each area. Provision was made for interconnecting the facilities of non-Bell companies with those of the Bell system, thus making possible the interconnection of nearly all telephones in the United States, as well as connections to the rest of the world. Service and rates are regulated by state utility commissions and the Federal Communications commission.

In the decade after 1954, the number of telephones in the world almost doubled—from about 90,000,000 to more than 170,000,000, divided about equally between the U.S. and other countries.

**2. Great Britain.**—Bell visited England and Scotland on his wedding trip in 1878 in the hope of developing a demand for the telephone. Despite the able support of Lord Kelvin, Sir William Preece and others, he aroused little public interest. He did, however, demonstrate his invention to Queen Victoria, who asked to purchase a pair of telephones and instead was presented with two instruments done in ivory. Interest was stimulated by this royal recognition, and the first telephone exchange was opened in London in 1879 with seven or eight subscribers. Several telephone companies were organized in various parts of Great Britain, but in 1880 the British courts held that the telephone system was legally a telegraph system under an antecedent law which made the telegraph a government monopoly under the postmaster general. The government officials, reluctant to assume the risks involved in developing this new form of communication, issued licences on a royalty basis to several private companies, which were later consolidated into a single company. A few municipal tele-

phone systems were also established under licence.

As the potentialities of telephone communication began to be appreciated, the government gradually took over the service. In 1896 the post office purchased the long-distance lines, and in 1902 it began establishing in London its own local telephone exchanges which were interconnected with those of the privately owned company. Finally, on Jan. 1, 1912, the post office acquired all the private telephone properties. Since then the post office has operated practically all telephones in Great Britain. When the Irish Free State was established, the British post office transferred to the Free State government its telephone system in southern Ireland. The British post office maintains a large research and development organization. Telephone apparatus is supplied by private companies that manufacture to post-office specifications.

**3. Germany.**—In Germany the telephone was a government monopoly from the beginning. Heinrich von Stephan, postmaster general and manager of the imperial telegraphs, when he learned about Bell's invention from an article in the *Scientific American*, ordered models for trial. After successful experiments at distances up to 90 mi. (Berlin-Magdeburg), he suggested on Nov. 9, 1877, to Bismarck, the imperial chancellor, that the telephone be used as an adjunct to telegraph service in rural post offices where there was not sufficient traffic to justify a trained telegraph operator. Within two years 800 villages were thus connected.

So it came about that in Germany the first public use of the telephone was for long-distance communication, telephones being found only in government post offices. The situation was therefore the reverse of that in the United States and Britain, where local exchanges came first. Later, as public demand forced the issue, exchange service was gradually introduced, starting in the larger German cities. In the German states of Bavaria and Württemberg, the telephone systems were operated by the state administrations until 1920, when they were transferred to the German post office.

**4. France.**—In France the telephone was first exhibited at the Paris exhibition in 1878, where it attracted little interest. The next year, however, the French telegraph officials, unwilling themselves to pioneer in this new field, granted concessions to several private companies which later consolidated into the Société Générale des Téléphones. This company initiated public telephone service in Paris in 1881 and subsequently in other cities. Starting in 1883, the French government established exchanges in various centres. In 1889 the government took over the entire private system, and after that time operated the telephone service.

**5. Switzerland.**—In Switzerland a privately owned telephone system was established under government concession in Zürich in 1880, while the government itself opened exchanges in Bern and Basel in 1881. Thereafter the government proceeded rapidly to establish new exchanges, and in 1886 purchased the Zürich system. After that time the Swiss government operated all telephones.

**6. Scandinavia.**—The Scandinavian countries have achieved a high degree of telephone development. In Sweden, the International Bell Telephone company of New York opened exchanges in Stockholm and Göteborg in 1880, and not long after in Malmö and elsewhere. In 1883 a competing telephone company was set up in Stockholm under the enterprising leadership of H. T. Cedergren. Co-operative telephone associations were established in Göteborg and in many rural communities. After a strongly competitive phase, in which the government participated, virtually all telephones were taken over by the state during the period 1890-1923.

The Swedish administration not only maintains a development organization, as do most other countries in Europe, but is unique among European telephone administrations in possessing factories for production of telephone equipment.

In Norway the International Bell Telephone company in 1880 secured franchises for Oslo and Drammen. The next year local companies established exchanges in several cities and a competing system in Oslo. Within ten years, largely through local enterprise, the telephone came to hold much the same place in Norwegian rural life that it does in the sparsely settled districts of the U.S. Ultimately the state acquired the more important local sys-

Canada.—Canada, divided by natural barriers and with most of its population concentrated near the long southern border,

**12. ITU and CCIF.**—Much of the progress in international telephone communication may be attributed to the work of international co-ordinating bodies. This work now centres in the Union Internationale des Télécommunications (UIT), called in English the International Telecommunication union, abbreviated ITU. This organization, now an agency of the United Nations, was founded in 1865 as the Union Télégraphique Internationale. The purposes of this organization as set forth in its charter are: "To maintain and extend international co-operation for the improvement and rational use of telecommunication; to promote the development of technical facilities and their most efficient operation, in order to improve the efficiency of telecommunication services, increase their usefulness, and make them, as far as possible, generally available; to harmonize the actions of nations in the attainment of those common ends." The ITU has a membership in about 90 countries and territories. The activities of the

FIG. 4.—U.S. OVERSEAS TELEPHONE CIRCUITS

ITU and its constituent bodies are financed by contributions from member governments.

For many years there were three permanent and essentially autonomous organs of the ITU: (1) the Comité Consultatif International Téléphonique (International Telephone Consultative committee), abbreviated CCIF, founded in 1924; (2) the Comité Consultatif International Télégraphique (International Telegraph Consultative committee), abbreviated CCIT, founded in 1925; and (3) the Comité Consultatif International des Radio Communications (International Radio Consultative committee), abbreviated CCIR, founded in 1927.

For implementing its work, each of these international consultative committees organized a number of study groups covering different phases of activity. A plenary assembly distributes questions to be investigated by the study groups. These work by correspondence or by meeting and submit their findings to the succeeding plenary assembly, which studies and discusses them and makes recommendations. Ordinarily the recommendations take the form of directives or rules which, without being mandatory, are usually observed by the technical and operating services of the government administrations and private operating agencies of the countries belonging to the union. The director of the consultative committee co-ordinates the work of the study groups, of the plenary assembly and of the committee as a whole.

The work of these committees has emphasized the importance of good engineering and transmission standards to world-wide communication service and has gone far in bringing about the introduction of such standards. In particular, exhaustive consideration has been given to problems of transmission and interference, frequency bands and allocations, standards of telephone performance and questions of suitable rates and classes of service, all of which has contributed to effective international long-distance telephony. On Jan. 1, 1957, the CCIF and CCIT were merged into a single committee known as the CCITT (Comité Consultatif International Téléphonique et Télégraphique).

### III. TECHNICAL DEVELOPMENT

The first telephones were extremely crude; it was barely possible to talk over them. The problems of transmitting speech for substantial distances were not understood, or even visualized. Nor was there the slightest comprehension of the complications involved in interconnecting large numbers of telephones.

One indispensable phase in the development of telephony was the improvement of telephone station instruments as to quality and loudness of speech, as well as convenience and cost. Concurrently, it was necessary to develop telephone lines and circuits to transmit speech currents reliably, without appreciable impairment or interference, and economically, for short or long distances. These advances are sometimes grouped under the term transmission development. Through such development, most telephone conversation has become practically effortless.

Another essential was the development of switching mechanisms whereby any two telephone instruments in a large system could be connected together certainly, rapidly and economically. This part of the advance is referred to as switching development. Progress in these areas came about gradually in different countries, along generally similar but not identical lines, and with, in many instances, substantial time differences.

**1. Station Instrumentalities.**—The station set at the premises of a telephone customer normally consists of a transmitter, which converts the speech waves in the air into their electrical replicas; a receiver, which performs the reverse operation of converting the incoming electrical waves into sound waves; a transformer (formerly called an induction coil) designed to increase the effectiveness of the transmitter and to permit full duplex operation (*i.e.*, use of a single pair of wires for speech in both directions, without requiring a switch to change from talking to listening or vice versa); a bell or equivalent summoning device; a switch hook to control connection of the set to the customer's line; and various associated items. In automatic switching systems the station set also includes a device, such as a dial, for generating signals to actuate the switching mechanism.

Bell's original electromagnetic transmitter served also as the receiver, the same instrument being held alternately to the mouth and the ear. An important forward step was the invention by Émile Berliner in 1877, and by Thomas A. Edison later in the same year, of different forms of transmitters utilizing variable-contact resistance between two solid electrodes connected in a battery circuit. Berliner employed metallic electrodes, while Edison used semiconducting materials, particularly plumbago (*i.e.*, graphite). Berliner also introduced the induction coil into the transmitter circuit in 1877.

The principle of the microphone contact (*see* MICROPHONE), which underlay both the Berliner and Edison transmitters, was elucidated by David E. Hughes in England in 1878. By virtue of this principle, energy from a battery is controlled by the voice waves so that the telephone transmitter acts as an amplifier as well as a converter of sound waves. The first recorded recognition of amplification through a microphonic contact seems to be found in a German patent of Robert Lüdtge, issued Jan. 12, 1878.

A transmitter in which granular carbon was used for the variable contact was invented in 1878 by Henry Hunnings, an English clergyman. Edison invented a transmitter whose carbon granules were obtained from anthracite coal, and Anthony C. White in 1890 invented the solid back transmitter, using a "button" of granular carbon placed between a fixed electrode and a diaphragm-actuated movable one. White's transmitter incorporated all the basic features of the modern telephone transmitter, though great improvements in efficiency (up to a thousandfold amplification of speech sounds), naturalness, resistance to aging and other features have resulted from continuing research and development. Extensive studies of the properties of speech and hearing have contributed to this result.

Modern telephone receivers utilize the same basic principles as those found in Bell's original instrument. Fundamentally, the receiver consists of a permanent magnet having pole pieces wound with coils of insulated fine wire, and a diaphragm driven by magnetic material which is supported near the pole pieces. Speech currents passing through the coils vary the attraction of the permanent magnet for the diaphragm, causing it to vibrate and produce sound waves. Through the years the design of the electromagnetic system has been continuously improved to provide better talking qualities. In a later type of receiver, introduced in the United States in 1951, the diaphragm, consisting of a central cone and ring-shaped armature, is driven as a piston to obtain efficient response over a wide frequency range.

In early telephone sets a hand-cranked generator, or so-called magneto, was used for signaling the operator, and local dry bat-

BY COURTESY OF THE BELL TELEPHONE SYSTEM

20th-century telephones: (above) one of the first dial telephones, 1919; (top right) "500" colour set with volume control for bell, 1954; (bottom right) pushbutton telephone

series supplied power to the transmitter. A centralized battery arrangement for signaling was invented in 1880 and one for both talking and signaling in 1886. With the gradual introduction of this common battery system, magneto telephone sets were largely superseded.

The first suggestions for mounting a telephone transmitter and receiver on a common handle, thus forming what is now known as a handset, were made by two Englishmen, C. A. McEvoy and G. E. Pritchett, in 1877. Starting in 1878, a type of handset devised by Robert G. Brown was used by boy operators in the Gold and Stock telephone exchange in New York city. Handsets for customers' use were introduced in France about 1882 and spread quickly in Europe. Initial difficulties in meeting satisfactory transmission standards with the handset arrangement were gradually overcome, and most modern instruments are of this type.

Methods of connecting the transmitter and receiver to the line likewise have been gradually improved. Starting with work by George A. Campbell, arrangements known as antiside-tone circuits have been developed whereby most of the electrical energy generated in the transmitter is directed toward the distant station, with a minimum entering the speaker's receiver.

Apart from the basic telephone instrument, special customer equipment and arrangements are provided to meet individual requirements of various kinds. Telephone sets are available which permit the user to hold a conversation without lifting the receiver, a small microphone being used to pick up the voice and a small loud-speaker to reproduce the incoming speech. There are loud gongs or other signaling devices for noisy locations, amplifiers for persons with subnormal hearing, automatic answering devices, arrangements for recording conversations, loud-speakers, etc.

Telephone pay stations installed in public or semipublic locations provide a coin telephone set which includes, in addition to the usual station equipment, a coin collector having one or more slots designed to accept legitimate coins and reject slugs or spurious coins. The coins, in passing down their respective slots, strike distinctive gongs whose tones permit an operator to supervise the deposits. Many coin collectors are arranged to hold the coins in suspension in a hopper, with means provided whereby the suspended coins can be collected or refunded, depending on whether or not the desired connection is completed.

Key telephone systems, affording greater flexibility of telephone usage than a single station set, are frequently used in business offices and residences. Combinations of push-button, turn-button or lever-type keys, installed on a desk or table or mounted integrally in the base of a telephone set, can be arranged to perform a variety of functions, particularly where two or more lines and a number of stations are involved. Thus a telephone may be connected to any of several lines, a call may be held on one line while conversation proceeds on another, etc.

**2. Telephone Lines.**—Telephone circuits are furnished principally by wire lines, although radio is used to a considerable extent. Telephone lines comprise a network of wires which interconnect individual telephone stations, central offices and communities. These wire lines are of two forms—cable and open wire. The usual type of cable consists of insulated copper wires, twisted together and usually covered with a protecting sheath. Open-wire lines consist of bare wires, generally of copper, fastened to insulators which are supported on poles at some distance above ground, commonly on pins in crossarms.

Following previous telegraph practice, the first telephone circuits utilized a single overhead wire, usually iron, with ground return. An important early improvement was the development by Thomas B. Doolittle in 1877 of hard-drawn copper wire that gave good tensile strength together with improved electrical conductivity. The advantages of a two-wire or so-called metallic circuit in reducing noise and interference were soon realized. It was found also that by transposing the wires (*i.e.*, interchanging their positions) a number of circuits could be carried on a single pole line without excessive interaction which would permit the conversation on one circuit to be heard on another. These several features made possible a successful open-wire telephone line between Boston and New York in 1885.

Early in telephone history, as the number of open-wire circuits strung on poles and rooftops in the large cities began to reach the point of impracticability, methods of compacting the lines in overhead or underground cable were tried. At first the wires were placed in pipes and sealed against moisture with oil, paraffin or asphaltum. Means were soon developed whereby lead, heated to plasticity, could be extruded over a core of conductors. The introduction of dry paper as insulation for the conductors completed the foundation for the modern telephone cable.

Research and development covering many materials and processes made it possible to increase the number of pairs in a full-sized local cable from a maximum of 50 in the year 1888 to more than 2,000 in the second half of the 20th century. This increase was accomplished largely by reducing the size of the copper wires, from 25 lb. per wire mile in 1888 to 4 lb. Following World War II, new types of cable sheath were developed in order to reduce cost and lessen dependence on lead supply. One form uses thin layers of aluminum and steel covered with polyethylene.

In a typical urban or suburban installation, insulated wires from each customer's premises extend to a distribution cable which in turn connects to a feeder cable leading to the central office. In densely built areas the feeders are generally placed in underground ducts; elsewhere, overhead. Circuits between central offices, known as trunks, are provided in trunk cables which usually employ larger wires than those leading to customer stations.

The network of lines which interconnect approximately 75,000 communities in the U.S. include approximately 35,000,000 mi. of wire on 260,000 mi. of route. More than 90% of the wires are in cable, the remainder open wire. For the rest of the world, the percentage of long-distance facilities furnished by cable ranges from nearly 100% in a few countries to a very low figure in the less populated regions. Since cable is virtually stormproof, it affords much greater reliability than does open wire.

A type of long-distance cable common in the U.S. employs conductors 36 mils in diameter, weighing 20 lb. to the mile (no. 19 AWG gauge). In making this cable, two paper-insulated wires are first twisted together to form a pair; then a quad is formed by twisting two pairs together. This twisting aids in the prevention of cross talk (*i.e.*, overhearing) between different pairs. In European toll cables, four conductors are usually twisted together to form a spiral four or star quad. In either case the quads are grouped together and enclosed by the sheath. Such a cable may be supported aerially or placed in an underground duct, or, with a suitable protective covering of jute or steel tape, may be buried in the ground. A special type of cable used for coaxial systems is discussed under *Carrier Systems* below.

**3. Phantoms.**—Around 1900 the principle of "phantoming" two pairs of wires was introduced. The original idea of phantoming was devised by Frank Jacob in 1882 and the present method by John J. Carty in 1886. The phantom arrangement makes it possible to derive from two pairs of wires a total of three telephone circuits. The additional circuit, called the phantom, is obtained by using the two wires of each pair in parallel as a side of the phantom. To render this scheme practical, efficient balanced transformers were needed for the end connections, and transposition arrangements were required to keep the cross talk between the three circuits within tolerable bounds. The phantom principle came to play an important part in both open-wire and cable plant. Because the presence of phantoms makes high-frequency transmission difficult, the advent of carrier systems greatly curtailed the use of phantoms for long-distance circuits.

**4. Loading.**—As speech currents pass along a line their strength decreases (a process referred to as attenuation), so that after some distance they become too weak to actuate a receiver properly. Studies by A. Vaschy (1889) and Oliver Heaviside (1893) developed the theoretical possibility of improving the transmission efficiency of telephone lines by artificially increasing their inductance. Various investigators speculated on the practicability of approximating the beneficial effect of an increase in uniformly distributed inductance by introducing in the line concentrated or lumped inductance in the form of low-resistance loading coils. Finally, in 1899, Michael I. Pupin and George A. Campbell (work-

ing independently, Pupin having a slight priority) discovered that the key to the problem was the spacing of the loading coils. By providing at least  $\pi$  (i.e., about 3.14) loading coils per wavelength at the highest frequency to be transmitted, a substantial reduction in the attenuation of the speech waves is obtained. Thus a cable circuit may, by means of coil loading, be made to transmit telephonic currents as efficiently as a nonloaded one whose conductors weigh many times as much.

Another way of adding inductance to a cable circuit was proposed by Carl Emil Krarup of Copenhagen, his idea being to wind helically along the copper conductor a fine wire of soft iron. A cable with this continuous loading was placed between Elsinore and Helsingborg in 1902. While continuously loaded cables have proved of some importance for submarine applications, coil loading has been almost universally preferred for loaded land cables.

By 1913 coil loading made it possible to extend the useful range of open-wire circuits to approximately 2,000 mi., and to employ underground cable to connect Washington, D.C., and Boston via New York city. After electron tube amplifiers became available, open-wire loading was largely abandoned, but loading is still extensively applied on cable circuits used for voice frequencies, and especially on local trunk circuits.

Satisfactory loading requires that the loading coils have very low energy losses in their magnetic cores and copper windings. The toroidal-shaped cores of modern loading coils make use of a powdered magnetic alloy whose particles are individually insulated, compressed under high pressure and then usually heat treated to develop optimum magnetic properties. Progressive improvement of magnetic core materials has brought about large reductions in the size and cost of loading coils, as well as improved performance. A core material commonly used in the U.S. consists of an alloy of nickel, iron and molybdenum known as molybdenum permalloy, discovered by Gustav W. Elmen. In Europe powdered iron cores of somewhat larger size are employed.

**5. Electron Tubes and Repeaters.**—For years the range of telephony was severely limited by loss of energy due to dissipation along wire lines, or to spreading in the case of radio waves. The idea of inserting one or more repeaters in a telephone line for the purpose of reinforcing or amplifying the telephonic currents from some local source of energy is almost as old as the telephone itself, but many years elapsed before the quest for a satisfactory repeater achieved success. In a so-called mechanical repeater, tried in 1904, inertia of the moving parts was found to present inherent limitations. Subsequently H. E. Shreeve developed a repeater employing carbon-contact amplification which was capable of practical use. The real solution to the amplification problem, however, was found in the device invented by Lee De Forest in 1906, which he called the audion, and which is now known as a three-electrode vacuum tube or electron tube, or in England as a valve. In its original form as used in radiotelegraphy, this tube was unsuited for telephone purposes (see ELECTRON TUBE; AMPLIFIERS). Research by Harold D. Arnold, Irving Langmuir and others showed that a major requirement for adequate performance in an amplifier was the creation of a high degree of vacuum inside the tube envelope. By 1914 satisfactory high vacuum tubes were produced. Using telephone repeaters with amplification supplied by vacuum tubes, telephone service between New York and San Francisco was inaugurated in 1915.

Continuing development work brought about many improvements in vacuum tube repeaters. Efficient circuits and auxiliary equipment were devised for utilizing the amplifier element and associating it with the line circuits. The life of the repeater tube most commonly used in 1917 was about 1,000 hours, whereas standard tubes of a type introduced in 1935 have a life of about 90,000 hours, equivalent to more than ten years of continuous operation. In addition, the power required to heat the tube filaments was reduced to one-tenth that required in 1917.

With repeaters available, transmission defects of different kinds became increasingly apparent. The lines, particularly if loaded, were found to introduce severe distortion by reason of differences in the transmission efficiency and transmission velocity at different frequencies. Furthermore, large variations in transmission loss

resulted from changes in the electrical resistance of cable conductors with temperature, or from changes in the leakage of open-wire conductors. Extensive developments in the field of network theory made it possible to design equalizers with frequency characteristics that compensate accurately for the line distortion. Variations in line loss are automatically counteracted by transmission regulators. Devices known as companders, in which the amplitude of speech syllables serves to compress the range of speech volumes at the transmitting end and to introduce a corresponding expansion at the receiving end, have proved beneficial in reducing the effect of line noise on both wire and radio circuits.

Another unwanted effect on telephone circuits is the presence of electrical echoes due to discontinuities in the line. These, when converted into sound, may disturb both talker and listener. The echoes become more annoying the longer they are delayed and hence are of greatest concern on long circuits. They are controlled by restricting their occurrence, by reducing the line delay or by applying devices called echo suppressors to prevent their reaching the telephone users.

The vacuum tube provided for the first time the means for precise measurement of these and other transmission effects, and thus made it possible to establish a firm foundation for the transmission art. Vacuum tubes connected as generators of electric oscillations supply the range of frequencies needed for communication measurement. Other vacuum tubes amplify the extremely weak currents involved in telephone transmission to a level at which they can be conveniently measured.

Following the three-element tube, many different types of vacuum tubes were developed for various applications. These include tubes with four or five elements for providing high and stable amplification, klystrons and traveling wave tubes for operation at extremely high frequencies, phototubes responsive to light, etc. Millions of cold-cathode, gas-filled electron tubes are used in telephone handsets attached to multiparty lines to permit ringing only the desired one out of four or more stations on a line. The normal life of such tubes is estimated to be hundreds of years.

**6. Carrier Systems.**—It is common practice on long-distance routes to multiply the circuit capacity by the application of carrier telephone systems. These are called carrier systems because of the underlying principle, known as modulation, whereby the voice frequencies modulate a higher frequency current which "carries" the voice currents. A voice wave is composed of undulations with a frequency of occurrence ranging from about 200 to 3,000 per second or, as it is commonly expressed, from 200 to 3,000 cycles per second (c.p.s.). In the modulation process these frequencies are transposed to a higher frequency range (e.g. 10,200 to 13,000 c.p.s.) for transmission over the line. By using different carrier frequency bands a number of conversations can be sent simultaneously over one transmission path. At the receiving end the carrier frequency bands are separated by electric networks called filters (invented by G. A. Campbell in 1915), and the original voice frequencies are recovered by an inverse process known as demodulation. Carrier systems make extensive use of vacuum tubes—as amplifiers, as oscillators for generating carrier frequencies and sometimes as modulators for shifting bands of frequencies from one range to another.

The art of multiplex carrier telephony grew out of the harmonic telegraph systems associated with the names of Gray, Bell E. Mercadier and others. The extension of the carrier principle to telephony, together with the use of electrical resonance instead of mechanical resonance for selecting the carrier frequencies, was accomplished in 1891 by two Frenchmen, Maurice Hutin and Maurice Leblanc. During the period 1908–11, demonstrations of carrier techniques were conducted by Ernst Ruhmer in Germany and Maj. Gen. George O. Squier in the U.S.

Following experiments between Toledo, O., and South Bend Ind., in 1917, the first commercial application of the carrier principle was made in 1918 on an open-wire line between Baltimore Md., and Pittsburgh, Pa., giving four additional telephone circuits on a pair of wires. With modern carrier techniques, as many as 16 telephone circuits are derived from a single open-wire pair. Beginning in 1934 in Germany, a system which yielded one extra

telephone channel on a lightly loaded cable pair was extensively applied in Europe.

Application of substantial numbers of carrier channels to cables necessitates many more repeaters because of the higher attenuation of the cable pairs, so that minor imperfections in each amplifier become quite serious. The solution to this problem was provided by Harold S. Black when he invented the negative feedback amplifier in 1927. The complete development of the underlying theory came in subsequent work by Harry Nyquist. Though difficult in theory, the idea itself is quite simple. A part of the amplifier output is fed back to the input in such a way as to give practically distortionless amplification, together with almost complete absence of variation in amplification as a result of power supply variation and tube aging. The improvement thus obtained may be a thousandfold or more.

The negative feedback principle is now applied almost universally to amplifiers used for any purpose. This principle formed the basis for the introduction in 1937, between Toledo and South Bend, of a 12-channel carrier system operating on nonloaded cable pairs. Today carrier systems are quite generally used on long-distance cable routes, yielding circuits with excellent transmission properties for distances up to thousands of miles. Important in this connection has been continued progress in the control of cross talk and noise. Cable carrier systems in the U.S. are arranged to derive 12 to 24 telephone circuits from two nonloaded 19-gauge pairs. Similar systems, some of them providing much larger numbers of channels, are used in Europe and elsewhere.

With the aid of a special type of cable conductor, called a coaxial unit or merely a coaxial, carrier techniques have been greatly expanded. A coaxial consists essentially of a copper tube, commonly about the size of a lead pencil, with a wire centrally supported inside. A full-size cable may contain as many as eight such coaxials, plus a number of conventional pairs of wire. By applying amplifiers at close intervals, four to eight miles, a very wide band of frequencies can be transmitted over a single coaxial.

The transmission properties of a coaxial circuit were considered by various 19th-century workers, especially Lord Kelvin and Alexander Russell. But it was a far journey from these studies to a wide-band transmission system suitable for long-distance multichannel telephony and television. The first such coaxial systems were applied in 1936 between New York city and Philadelphia and between Berlin and Leipzig. More highly developed systems are now widely used in both the U.S. and Europe.

A type of coaxial system introduced between Minneapolis, Minn., and Stevens Point, Wis., in 1939 utilizes a frequency band nearly three megacycles (*i.e.*, 3,000,000 cycles) wide, with two coaxials giving either 600 two-way telephone channels or a television circuit in each direction. Techniques were further augmented in a system, first applied in 1952, which provides a frequency band nearly eight megacycles wide, so that two coaxials can provide either (1) 1,800 telephone channels; or (2) 600 telephone channels plus a 4.2-mc. television circuit in each direction. Since a long coaxial system may have 1,000 or more repeaters connected in tandem, each one providing a ten-thousandfold amplification, the utmost perfection is necessary in the performance of each repeater.

The minimum distance for which carrier systems prove economical depends on the cost of the terminal apparatus. In recent types of systems the economical distance has been greatly reduced, so that carrier can be used for short-haul toll circuits, interoffice trunks and rural circuits.

**7. Radio.**—Radio, originally employed for telegraphy, has become an important instrument for telephone purposes. Both the theoretical and the utilitarian aspects of radio transmission are treated elsewhere (*see* BROADCASTING; RADIO).

The same basic principle of modulation used in carrier systems is required to shift the telephone signals to the desired radio frequency. There are several different kinds of modulation that may be used in either radio or wire systems. Simplest of these is amplitude modulation, in which the amplitude of a modulating wave (*e.g.*, a speech wave) controls the amplitude of a sine wave carrier. The first complete analysis of amplitude modulation was

made by John R. Carson, who showed that in order to convey the intelligence only one of the bands of frequencies generated in the process need be transmitted. Because of its efficient use of frequency space, Carson's single side band method is widely employed.

Another common form is frequency modulation, wherein the instantaneous frequency of a sine wave carrier is varied in proportion to the amplitude of the modulating wave. This method makes it possible by sacrificing frequency space to gain an advantage in the ratio of signal to noise.

Still another form is pulse modulation, in which the carrier consists, not of a sine wave, but of a series of pulses whose amplitude, duration, position or mere presence may be controlled so as to convey the message. In pulse code modulation, originated by A. H. Reeves in 1939, successive quantized samples of the modulating wave produce corresponding code patterns of pulses. This provides, at the expense of band width, low vulnerability to noise and interference and adaptability to repeated regeneration of the signals without distortion. For multichannel transmission, the pulses corresponding to different channels are interleaved.

The advantages of being able to telephone without a wire connection were obvious from the beginnings of radio. Many early radio experimenters, notably R. A. Fessenden and De Forest in America and Quirino Majorana, Giuseppe Vanni and V. Poulsen in Europe, succeeded in transmitting speech over distances of a few miles. Several essentials for practical application were lacking, however—a practicable generator of continuous high-frequency waves, a means for modulating these waves in accordance with speech and a receiving amplifier for revivifying the waves after enfeeblement in transit. In the main, it was the vacuum tube that provided the solution for all these problems.

In 1915, the same year that telephone service across the U.S. was begun, intelligible speech was experimentally transmitted by radio from Arlington, Va., to Hawaii and to Paris. In 1927 the first commercial overseas radiotelephone circuit was opened between the U.S. and England. Service from Berlin to Buenos Aires, Arg., was begun in 1928, from England to South America and Australia in 1930, and service between the U.S. and South America, Central America, the Hawaiian Islands, the Philippine Islands, the Netherlands Indies and Japan during the years 1930 to 1934. In the 1960s radiotelephone service was available between all principal countries not connected by wire and in addition was used in many instances to supplement wire facilities. Most of the overseas radiotelephone circuits were in the short-wave range from 3 to 30 mc., where long-distance transmission is accomplished by reflecting the waves from the ionosphere. The performance of the radio circuits, although fairly satisfactory, was subject to some difficulty due to atmospheric disturbances.

Radio systems that make use of scattering from the tropospheric layer in the atmosphere can transmit wide frequency bands capable of handling a number of telephone channels to distances "beyond the horizon." A system of this type was placed in service between Miami and Havana in 1957.

Starting with service to the steamship "Leviathan" in 1929, radiotelephone service has been extended to many large oceangoing ships. Thousands of smaller ships in coastal waters, on lakes, in harbours and on rivers are equipped for connection to shore telephone stations by radio. Commercial radiotelephone service between the public telephone system and motor vehicles in cities and on highways began in the U.S. in 1946. Other vehicles were provided with radiotelephone sets for private services, such as those of airlines, police, taxicabs, etc., and there were mobile radio stations for public service on trains and airplanes. Radio systems were used also for bridging short water gaps and crossing other difficult terrain. Portable radiotelephone equipment was employed in emergencies such as floods or hurricanes to bridge gaps in the regular toll circuits until normal service could be restored. Radio paging systems were available in which a small receiving set carried on the person was used to summon an individual to the nearest telephone in order to receive a call.

Repeated radio systems for obtaining substantial numbers of long-distance telephone circuits, as well as broad frequency bands for television transmission, are used in many parts of the world.

These commonly transmit radio waves of thousands of megacycles, known as microwaves, over line-of-sight paths. As early as 1934 a microwave radio system developed by A. G. Clavier and others was employed for transmission across the English channel. The large-scale development during World War II of microwave techniques for radar use provided a powerful stimulus in the postwar development of microwave communication systems. A microwave radio-relay (*i.e.*, repeated) system was placed in service between New York city and Boston in 1947, and one across the United States in 1951. This latter system provides six radio channels in each direction, and each radio channel affords either 600 telephone circuits or a single television circuit.

Concentration of large numbers of circuits on a single route by means of carrier systems, coaxial systems or radio-relay systems yields large economic advantages through sharing common elements of cost including right of way, line conductors, installation, line maintenance, radio towers, power supply, etc. Combining the requirements for both telephony and television on a common route affords further economy.

**8. Submarine Telephony.**—Submarine cables for transmitting telegraph signals antedated the invention of the telephone. Many years went by, however, before long submarine cables suitable for telephony became practical. As early as 1891 a cable containing four wires was laid under the English channel, between St. Margaret's bay, Eng., and Sangatte, Fr. During the next five years several cables of similar construction, suitable only for shallow water and relatively short distances, were placed under the channel.

When cable is laid in deep water, the high pressure necessitates a different type of cable, the usual construction for deepwater telephone cables consisting of a central conductor surrounded by insulation around which is a return conductor. The first such cables were laid in 1921 between Key West, Fla., and Havana, Cuba, a distance of more than 100 mi. Each of these cables provided a single voice circuit and four telegraph circuits. Two years later the first long submarine cables adapted for carrier telephone transmission were placed across the 40-mi. stretch between the California coast and Santa Catalina Island.

For spanning greater distances with the wide frequency band required to accommodate a number of telephone channels, intermediate repeaters are needed. The first submerged telephone repeaters were applied between Anglesey, Wales, and the Isle of Man in 1943 and between Lowestoft, Eng., and Borkum, Ger., in 1946. These repeaters were adapted only for shallow-water operation. Repeaters designed for deepwater use were included in a pair of cables placed in 1950 between Key West and Havana, the two cables giving a total of 24 telephone circuits.

To handle the expanding requirements for transatlantic telephone service, the first transoceanic telephone cable system, between Clarendville, Nfd., and Oban, Scot., with an extension from Newfoundland to Nova Scotia and a radio-relay link to Portland, Me., was placed in service in 1956. This was a joint project of the American Telephone and Telegraph company, the British post office and the Canadian Overseas Telecommunication corporation. The two cables on the main crossing had submerged repeaters at approximately 40-mi. intervals to provide a total of 36 telephone circuits. The vacuum tube repeaters were designed to operate continuously and flawlessly with

no attention for at least 20 years, at depths up to 2,000 fathoms. Similar submarine systems between Port Angeles, Wash., and Ketchikan, Alaska, and between California and Hawaii are in service. The first cable (5,300 nautical miles) between Hawaii and Japan (1964) provided 128 voice circuits, the same number provided in 1965 by a cable linking New Jersey with France.

**9. Information Theory.**—Progress in telephony and allied arts was greatly furthered by the formulation of a comprehensive theory underlying the communication of information. This theory, variously referred to as information theory (*q.v.*) or communication theory, resulted from studies by Claude E. Shannon, Norbert Wiener and others, following earlier work by R. V. L. Hartley. It states in essence that information of the kind contained in messages transmitted over communication systems is measurable; as a consequence, the loss of information caused by unpredictable perturbations (noise) introduced during transmission can be evaluated. The basic unit of measure is a "yes-or-no" choice, which is called a bit (short for *binary digit*). All information can for communication purposes be expressed as, or encoded into, sequences of on-or-off (*i.e.*, binary) pulses. The development of the basic mathematical theory made it possible to treat transmission factors such as band width, noise, distortion and the like, and the relations among them, in quantitative terms. This facilitated the comparison of different transmission systems—for example, systems using different forms of modulation, different coding etc. The theory also established upper limits for the rate at which information can be transmitted over systems of different kinds.

**10. Switching.**—Establishing a connection between any two telephones out of a large group is a complicated process. Even in the simplest situation, where both telephones are served by the same switchboard, it is necessary to: (1) observe that a customer wishes to make a call; (2) connect the operator (or switching mechanism) to his line; (3) determine what telephone he wishes to be connected with; (4) select a speech path between them which is not already in use; (5) determine whether the wanted telephone is idle or busy; (6) if idle, ring the bell, or if busy, inform the calling customer; (7) determine when the call has ended; and (8) restore all equipment to its quiescent state, in readiness for other calls. If the telephones are served by different switchboards, perhaps in widely separated cities, it is also necessary to determine what switchboard serves the wanted telephone and how it may be reached.

From the beginning, the importance of the switching function in telephony was recognized, but the means initially employed were

BY COURTESY OF THE BELL TELEPHONE SYSTEM

#### CENTRAL-OFFICE SWITCHING SYSTEMS

(Left) Step-by-step switches; (centre) crossbar switches; (right) logic units for electronic switching

primitive. The first telephone switching arrangement was provided by the Holmes Electric company at Boston in 1877, by using for telephone connections in the daytime the line wires and plug-and-block connectors employed for a burglar alarm system at night. A commercial telephone switchboard placed in operation at New Haven, Conn., in 1878 served 21 stations on eight grounded lines. In contrast, a modern central office may serve as many as 100,000 telephones on 50,000 lines.

The New Haven exchange, and other primitive ones, provided a separate switch for each combination of lines that might have to be connected together. For eight lines this required only 28 switches; but the number of switches increased much more rapidly than the number of customers and quickly became impracticable. With 100 lines, for example, 4,950 switches would have been required. To get around this difficulty, the cord circuit was introduced in 1880. Each line was terminated on the switchboard in a socket (called a jack), and a number of short flexible circuits (called cords) with a plug on each end were also provided. Two lines could thus be interconnected by inserting the two ends of a cord in the appropriate jacks. This was an efficient system as long as the number of calls passing through a switchboard could be handled by a single operator.

Another early invention, which permitted much larger volumes of traffic to be handled efficiently on a manual basis, was the multiple system devised by Leroy B. Firman in 1878. With this, each customer's line is connected to a number of jacks, placed at suitable intervals along the switchboard, so that one is within the reach of every operator.

With the introduction of the multiple system, it became necessary to develop a busy test to determine whether or not a line with which connection was desired was already in use through a connection made at some other part of the switchboard. In a manual switchboard the operator performs this test by touching the tip of a connecting plug to a conducting sleeve forming part of the jack of the desired line. If the line is busy, a click is heard in the operator's receiver.

In 1895 the magnetically operated drop signals which informed the operator of a customer's desire for service were first replaced by incandescent lamps. These were more reliable and smaller than the drop signals and permitted a much more compact arrangement of the subscriber's jacks.

There was continuous improvement to adapt manual switchboards to the growing volume and complexity of telephone traffic and to modern standards of workers' comfort and of customers' convenience. There also were improvements in the associated circuits. But the design of all subsequent manual switchboards was based upon the plug-ended cord, the multiple, the busy test and lamp signals.

The idea of fully automatic switching also appeared quite early. In fact the first patent for an automatic switching system was issued to Daniel Connolly, T. A. Connolly and T. J. McTighe in 1879, only two years after the first primitive switchboard in Boston. This system never achieved commercial success. In 1889 Almon B. Strowger invented an automatic system which was installed at La Porte, Ind., in 1892, the first commercial automatic exchange in the world. The system was subsequently developed by Alexander E. Keith and other engineers of the Automatic Electric company into a form which is still extensively used throughout the world under the names step-by-step or Strowger system. In this system the switching mechanisms are operated directly by pulses generated at the customer's instrument. Originally the customer operated a push button to produce the switching pulses, but this and other types of calling devices gradually gave way to the dial mechanism now in general use. This was invented in 1896 by A. E. Keith, C. J. Erickson and John Erickson of the Automatic Electric company.

The basic mechanism around which the Strowger system is built is the Strowger switch, which is sometimes called a connector and sometimes a selector according to the use to which it is put. In complete form this consists essentially of two parts: a ten-by-ten array of terminals (the bank) arranged in a cylindrical arc; and a movable switch (the brush) which is translated along the axis of

the cylinder by one ratchet mechanism and rotated about it by another, so that it can be brought to the position of any one of the 100 terminals. Each ratchet mechanism is driven by an electromagnet, which can respond to the pulses produced by a telephone dial.

Many other switching systems have been invented, notably in the United States, Germany and Sweden, and a number of them have been put into successful commercial operation. Some of these have operated on the step-by-step principle but have used different types of apparatus. Others have operated on the principle of common control, in which pulses are stored for a short time in a device which then controls the switches either directly or through some intermediate mechanism.

The distinguishing feature of such systems is that the common-control mechanisms (known as registers, senders, translators, directors, markers, etc.) are not assigned to the customer for the duration of his call but are used only as long as they are needed and are then free to serve other customers. Thus each serves many calls per hour, and few are required; it is therefore practicable to provide complicated devices which can perform a variety of useful functions but which would be too expensive to assign for the duration of the call. Systems using common control have great flexibility and efficiency in the use of trunk groups, and are especially advantageous for large exchanges and for automatic routing of long-distance calls.

The earliest common-control systems were developed by the Western Electric company, primarily to meet the needs of large metropolitan centres. In a program beginning in 1906, two systems were developed alongside one another, and both proved to be successful. One, called the rotary system, was first put into commercial service in England in 1914. The other, called the panel system, went into commercial use at Newark, N.J., in January of the following year. Common-control principles were also applied to the step-by-step switch by the Automatic Electric company, and the resulting system was adopted by the British post office in 1922 for use in London. The more recent common-control systems have been crossbar systems, of which several commercial types have been developed by the Bell system in the United States, by the Swedish Telecommunication administration and the L. M. Ericsson company in Sweden and by subsidiary companies of the International Telephone and Telegraph company in Belgium and Germany.

The most important concepts in the evolution of the modern types of crossbar exchange were probably translation, the sender, the marker, the crossbar switch and the principle of call-back operation. Translation, invented by E. C. Molina of the American Telephone and Telegraph company in 1906, makes it possible to convert incoming dial pulses from decimal to nondecimal form and thus affords flexibility and efficiency in the use of trunk groups. The sender, first used in the rotary system, is essentially an automatic mechanism which generates new dialing signals, either in the code given by the translator or in other appropriate codes.

The basic function of the marker is to make a preliminary test of several alternative paths to a wanted destination through an array of switches, before any of the switches is closed, so as to avoid the possibility of encountering a busy switch after part of the switching operation has been performed. It was invented by N. G. Palmgren and G. A. Betulander of Sweden in 1912 and was first used commercially in a system manufactured by the Relay Automatic company of England from 1915 to 1920. As used in crossbar systems of the Bell system, it has been developed into a complex assemblage which serves as the basic control element for the entire switching operation. Among other things, it tests the circuits before connections are established; it seeks out alternate paths when needed; and it reports trouble conditions which may be encountered in its preliminary tests. Since it can examine a large number of trunk circuits practically simultaneously, it uses them with great efficiency.

The crossbar switch is essentially a multiple relay structure affording fast operation and reliable contacts of precious metal. Unlike other switches mentioned above, the moving parts have little inertia and move through small distances. It was first con-

ceived in America by Homer J. Roberts of Automatic Electric company in 1901, and later patented in separate forms by John G. Roberts and John N. Reynolds, both of Western Electric company. The first satisfactory mechanical design, worked out by Palmgren and Betulander in Sweden in 1919, was used by the Swedish telephone authorities in a commercial exchanger in 1926. Aside from a small-scale trial installation in Stockholm in 1919, which was subsequently abandoned, this was the first public use of the crossbar switch. The system in which it was used, however, and all other crossbar exchanges in Sweden until about the middle of the century, operated on step-by-step principles. Most of the crossbar switches used in America and other countries follow the Swedish design.

Call back is a principle of operation, invented by Edson L. Erwin in 1938, which has been effectively used in crossbar systems. When a customer originates a call, the register stores not only the wanted number but also the identity of the calling telephone, which is determined automatically. The connection with the calling subscriber is then disconnected, and an entirely new connection established, from a favourable point within the exchange, to both the calling and wanted telephones.

All the automatic switching systems described were built around the electromagnetic relay and other electromagnetically operated devices. The relay employs magnetic attraction produced by an electric current to move a magnetic armature and thus open or close electrical contacts so as to perform switching or other operations. This device dates back to the early part of the 19th century, and in a form much cruder than the present was the basis for the development of telegraphy. The name relay results from the early use of the device to pass along telegraph signals after enfeeblement in transmission. As switching systems developed, relays came to be employed for a wide variety of purposes, including multiple contacts, slow or fast operation or release, marginal operation, etc. Modern switching systems require approximately 1,000 relay operations to establish a single telephone connection, and some systems have as many as ten relays per subscriber. Hence, reliability in relays is extremely important. Less than one failure in 40 years of service is a normal criterion for satisfactory operation.

As automatic switching systems were improved, their application was extended until, by the 1960s, more than 90% of the world's telephones were automatic, as compared with 15% only a generation earlier. This metamorphosis occurred not only because automatic operation is faster, more accurate and more economical than manual service, but more basically because in many areas the enormous number of operators necessary to support the rapid telephone growth would have far exceeded the possible supply.

In America the crossbar system, designed originally for metropolitan areas, presented so many advantages as compared with earlier automatic systems that its basic principles were soon applied in other fields. Crossbar tandem equipment, for example, is the modern version of the tandem principle developed originally for manual systems. Through the tandem scheme, traffic between offices on opposite sides of a large metropolitan area is handled through one or more intermediate (tandem) offices which act as clearinghouses for these relatively small amounts of traffic, handling them more efficiently than if direct paths were provided and thus reducing the number of trunk circuits required.

Another type of crossbar system is specially adapted to the automatic switching of long-distance circuits. With this, connections are made on a two-path or four-wire basis, a separate path being used for each direction of transmission so as to obtain superior transmission performance on connections comprising a number of circuit links in tandem.

The first crossbar switching system in the long-distance field, introduced in Philadelphia in 1943, enabled operators but not customers to dial long-distance calls. This advance was followed by another which permitted direct dialing by customers without the aid of an operator. The switching mechanism selects the route to the distant telephone. Should it find all direct circuits busy, it explores in succession as many as five alternate routes, and estab-

lishes the connection along the least circuitous one available. All this is done automatically. Necessary information regarding direct and alternate routes to the destination is permanently available in a translator, which supplies it to the control circuits as required.

Arrangements for customer dialing of at least some intercity calls were provided in all the principal countries of the world by the mid-1950s. In North America a complete program was worked out for eventually handling substantially all calls in this way. The initial installation of equipment to permit nation-wide dialing by customers was placed in service at Englewood, N.J., in 1951. With this equipment, customers were able to dial directly about 11,000,000 other customers in selected areas as far away as San Francisco. They dial a three-digit area code followed by the digits of the directory listing of the called number. By the mid-1960s this type of service had been extended to more than 83% of the Bell system telephones.

Closely related to automatic switching is the automatic recording of data for preparing the customer's bill. The simplest means for this purpose, used in either manual or automatic offices, is an electromechanical counter, known as a message register, which records the number of calls made by a customer. In a more elaborate arrangement, referred to as multiunit registration, the register can be operated more than once for a single call, the number of operations depending on the distance and duration of the call. Each customer is billed on a bulk basis for all of the "message units" totaled on his register. This plan is widely used in America and almost universally elsewhere. Another method of charging is "automatic ticketing," first introduced in Belgium. With this method, automatic equipment prints for each call a ticket similar to one that might be prepared by an operator.

In the U.S., where distances are great and the tariff structure complicated, a highly versatile type of message registration system, called automatic message accounting (usually abbreviated to AMA), was developed. In this system the information needed for billing calls is recorded in the form of coded holes in paper tape. Automatic processing of the tapes in an accounting centre yields bills with any desired amount of detail. The AMA system is extensively used in association with direct distance dialing.

A big step in the improvement of telephone service in outlying areas resulted from automatizing the telephone switching in very small communities. Community dial offices, either of the step-by-step or all-relay type, were provided in many localities. These function with no attendance except for occasional maintenance visits.

Another phase of telephone switching is found in switchboards, known as private branch exchanges, which are located on the customer's premises. The private branch exchange (abbreviated PBX) serves both for interconnecting the station sets of the customer's establishment and for connection over trunk lines to the central office. The smaller PBX's can be placed on a desk and operated by a person who may perform other duties as well. Large PBX's resemble central office switchboards and may be of either the manual or automatic type.

Exploratory developments are well under way in the principal communications laboratories of many countries with the ultimate objective of replacing electromechanical switching systems with electronic ones. A small beginning had been made in some units that are partly electronic and partly electromechanical. Among these may be mentioned the mechanoelectric system developed by the International Telephone and Telegraph company in Belgium and first installed at Ski, Nor., in 1954. By the mid-1960s fully electronic switching systems had been introduced in the U.S.

**11. Associated Services.**—Much of the plant required for telephone service is well adapted to the provision of other types of communication service, so that economies usually can be effected by designing the plant to handle the combined requirements of different services. The earliest of such associations was with the telegraph. Direct-current telegraph channels superposed on the telephone wires were leased to private customers and to the companies furnishing message telegraph service, and were employed also for telephone line maintenance. The introduction of carrier

transmission methods made it possible to derive as many as 18 telegraph channels from one telephone circuit. Such channels serve both for teletypewriter exchange service, which is a switched service analogous to telephone service, and also for private-line teletypewriter service.

Satisfactory picture transmission requires a frequency band of about the same width as that for telephone conversation. Special networks are provided for picture service, and occasional use is made of regular telephone circuits for this purpose. Telephone circuits are employed also to render facsimile and other services. High-speed transmission of information in the form of pulses is being increasingly applied for both commercial and military purposes. Generally speaking, the chain networks used for the radio broadcasting of either sound or television programs are provided in conjunction with the telephone plant. For good quality of music reproduction, a frequency band somewhat wider than that adequate for speech is required. Television broadcasting necessitates a very wide frequency band, equivalent to that required for about 1,000 telephone circuits.

Television circuits are derived, commonly in association with large numbers of telephone channels, from coaxial or microwave systems. Wire broadcasting systems, in which sound programs are conveyed by wire directly to the customers' premises, are in limited use.

**12. Later Advances.**—Foremost in the area of new art in the industry is the transistor (*q.v.*), invented by W. H. Brattain and John Bardeen and first announced in 1948. This is a three-electrode amplifying device employing a semiconductor such as germanium or silicon. An improved form, known as the junction transistor, was invented later by William Shockley. The transistor can perform many of the functions previously assigned to vacuum tubes but is far more efficient because it requires no power to heat a cathode. Furthermore, it operates with much lower electrode voltages and is much smaller than a vacuum tube. Because of the transistor's low power dissipation and low voltage requirements, other electronic components associated with it can be miniaturized. The overall result is that the size, weight and power consumption of apparatus employing transistors usually can be reduced to a small fraction of that for equivalent apparatus using vacuum tubes.

Transistors therefore find large and varied applications in almost every field of electronics, and particularly in telephony and associated services, including not only places where vacuum tubes were previously used but many new situations as well. Thus transistors promised economies through more extensive use of amplification and carrier techniques in the local telephone plant.

In contrast with relays and other electromagnetic devices which require a minimum of several thousandths of a second to operate, electronic devices such as the transistor may be used to perform switching operations with a speed of the order of a few millionths of a second. Besides being faster, the electronic devices also are capable of performing more complex operations involving choices based on conditions existing at the instant. This means that no longer must a large complement of apparatus be set aside to serve a customer during the entire period of his call, or even a large part of it. The extremely high speed was expected to afford substantial economies in new switching systems through centralizing of functions and time sharing of the apparatus used for establishing connections. The common apparatus would serve a large number of customers in such rapid succession that each one received the equivalent of continuous and exclusive service. Reduction of space and power requirements would yield further economy. Altogether, the new art of solid-state electronics provided the basis for a revolution in both switching and transmission technology.

Research on the use of hollow wave-guide conductors as transmission lines promised new long-distance systems that would transmit extremely wide bands of frequencies, of the order of thousands of megacycles, to provide a great multiplicity of communication channels. Intercontinental submarine cables with amplifiers capable of handling large numbers of telephone channels promised to be of increasing importance to world communication. Radio communication via artificial satellites, such as the commercial

service inaugurated by the Early Bird satellite in 1965, offers potentialities for providing wide transmission bands for communication across oceans. Such bands might be used for television or other visual presentations, or for telephone or data communication. There might be (1) a number of relatively low-altitude satellites (2,000–3,000 mi. high) each serving as a passive reflector, or (2) one or more satellites equipped for use as an active relay station. There is special interest in an active satellite placed about 22,300 mi. above the equator with an orbital velocity enabling it to remain above the same spot on Earth. (See further *SPACE EXPLORATION: Applications: Communications Satellites.*)

As to telephone service in general, there are no indications of saturation in demand, even in highly developed areas. Substantial further growth in number of telephones and their utilization is therefore in prospect. Large expansion could also be envisioned in services associated with telephony—such as those provided by video telephones (opened in limited commercial service in the U.S. in 1964).

**TELESCOPE**, an optical instrument employed to view distant objects (*Gr. tele, "far," skopein, "to see"*).

**Early History.**—The telescope was invented in Holland about 1608. The credit has been attributed variously to three individuals, Hans Lippershey and Zacharias Janssen, spectacle makers in Middelburg, and James Metius of Alkmaar (brother of Adrian Metius, the mathematician). The traditional story is that Lippershey, happening while holding a spectacle lens in either hand to direct them toward the steeple of a neighbouring church, was astonished on looking through the nearer lens to find that the weathercock appeared nearer. Accordingly he fitted the lenses in a tube to preserve their relative distance and thus constructed the first telescope.

Telescopes were made in considerable numbers and found their way over Europe soon after their invention. Galileo states that, happening to be in Venice about May 1609, he heard that a Belgian had invented a perspective instrument for making objects appear nearer and larger. The day after his return to Padua he made his first telescope by fitting a convex lens in one end of a leaden tube and a concave lens in the other end (*see LENS*). A few days afterward, having succeeded in making a better telescope, he took it to Venice, where he communicated the details to the public and presented the instrument itself to the doge Leonardo Donato. The senate, in return, settled him for life in his lectureship at Padua and doubled his salary, which previously had been 500 florins. Galileo devoted much of his time to improving the telescope. He conquered the difficulties of grinding and polishing the lenses, and soon succeeded in producing telescopes of greatly increased power. His first telescope magnified 3 diameters; he soon made instruments magnifying 8 diameters, and finally one magnifying 33 diameters.

With this last instrument Galileo discovered in 1610 the satellites of Jupiter, and soon afterward the spots on the sun, the phases of Venus, and the hills and valleys on the moon. He demonstrated the revolution of the satellites of Jupiter round the planet, and gave rough predictions of their configurations, proved the rotation of the sun on its axis, established the general truth of the Copernican system as compared with that of Ptolemy, and fairly routed the fanciful dogmas of the philosophers. These bril-

liant achievements, together with the immense improvement of the instrument under the hands of Galileo, overshadowed in a great degree the credit due to the original discoverer, and led to the universal adoption of the name of Galilean telescope for the form of instrument invented by Lippershey.

In the Galilean telescope the object glass is a convex lens and the eyepiece concave (see fig. 1). Johannes Kepler was the first to explain the theory and some of the practical advantages of a convex eyepiece (see fig. 2) in his *Dioptrice* (1611). The first person who actually constructed a telescope of this form was the Jesuit Christoph Scheiner, who gives a description of it in his *Rosa Ursina* (1630). William Gascoigne pointed out one great advantage of the form of telescope suggested by Kepler, viz., the visibility of the image of a distant object simultaneously with that of a small material object placed in the common focus of the two lenses. This led to his invention of the micrometer and his application of telescopic sights to astronomical instruments of precision. It was not till about the middle of the 17th century, however, that Kepler's telescope came into general use, and then, not so much because of the advantages pointed out by Gascoigne, but because its field of view was much larger than that of the Galilean telescope. The first powerful telescopes of this construction were made by Christiaan Huygens, after much labour, assisted by his brother. With one of these, of 12-ft. focal length, he discovered the brightest of Saturn's satellites (Titan) in 1655, and in 1659 he published his *Systema Saturnium*, in which was given for the first time a true explanation of Saturn's ring, founded on observations made with the same instrument.

FIG. 1.—DIAGRAM SHOWING COURSE OF RAYS WHEN THE EYE LENS IS CONCAVE (OR NEGATIVE)

Because of the imperfections of the single objective lens it became essential to increase the focal length when high magnifying power was required. G. D. Cassini discovered Saturn's fifth satellite (Rhea) in 1672 with a telescope of 35 ft. and the third and fourth satellites in 1684 with telescopes made by M. Campani of 100- and 136-ft. focal length. Huygens states that he and his brother made object glasses of 170- and 210-ft. focal length, and he presented one of 123 ft. to the Royal Society of London. Adrien Auzout (d. 1691) and others are said to have made telescopes of from 300- to 600-ft. focus, but it does not appear that they were ever able to use them in practical observations. James Bradley, on Dec. 27, 1722, measured the diameter of Venus with a telescope whose object glass had a focal length of 212½ ft. In these very long telescopes no tube was employed. They were termed aerial telescopes.

**Early Reflecting Telescopes.**—It was not until mid-18th century that these unwieldy instruments were supplanted by the achromatic telescope. Meanwhile the refracting type of telescope had a rival in the reflecting telescope invented by Sir Isaac Newton. It was, in fact, Newton who discovered what was the trouble with the refractor which led to the need for excessive length. It had been supposed that the only imperfection in the image arose from the error known as spherical aberration, and the efforts of opticians were concentrated on devising lenses of suitable forms of curvature to correct this. In 1666 Newton discovered the different refrangibility of light of different colours, and he soon perceived that the fault of the refracting telescope was that the light of different colours followed different paths; so that if, for example, the telescope was focused sharply for blue light—the green image would be altogether out of focus and blurred. He overhastily concluded from rough experiments (*Optics*, book i, part ii, proposition 3) "that all refracting substances diverge the prismatic colours in a constant proportion to their mean refraction." If this were true no combination of refracting substances could bend the path of the light without introducing colour, and therefore no improvement could be expected in the refracting telescope. He therefore turned his attention to the construction of reflectors. The form later known as the Gregorian reflector had been proposed by James Gregory in

1663; but he had not succeeded in constructing the instrument practically.

Newton, after much experiment, selected an alloy of tin and copper for his specula, and he devised means for grinding and polishing them. He did not attempt the formation of a parabolic figure on account of the probable mechanical difficulties, and he had besides satisfied himself that the chromatic and not the spherical aberration formed the chief fault of previous telescopes. Newton's first telescope so far realized his expectations that he could see with its aid the satellites of Jupiter and the horns of Venus. Encouraged by this success, he made a second telescope of 6½-in. focal length, with a magnifying power of 38 diameters, which he presented to the Royal society in Dec. 1671. A third form of reflecting telescope was devised in 1672 by N. Cassegrain. No further practical advance appears to have been made in the design or construction of the instrument till the year 1723, when John Hadley (best known as the inventor of the sextant) presented to the Royal society a reflecting telescope of the Newtonian construction, with a metallic speculum of 6-in. aperture and 62½-in. focal length, having eyepieces magnifying up to 230 diameters. The instrument was examined by James Pound and Bradley, the former of whom reported upon it in *Philosophical Transactions*, 1723.

Bradley and Samuel Molyneux, having been instructed by Hadley in his methods of polishing specula, succeeded in producing some telescopes of considerable power, one of which had a focal length of eight feet; and, Molyneux having communicated these methods to Scarlet and Hearn, two London opticians, the manufacture of telescopes as a matter of business was commenced by them. However, it was reserved for James Short of Edinburgh to give practical effect to Gregory's original idea. Born at Edinburgh in 1710 and originally educated for the church, Short attracted the attention of Colin Maclaurin, professor of mathematics at the university, who permitted him about 1732 to make use of his rooms in the college buildings for experiments in the construction of telescopes. In Short's first telescopes the specula were of glass, as suggested by Gregory, but he afterward used metallic specula only, and succeeded in giving to them true parabolic and elliptic figures.

**Achromatic Telescopes.**—The historical sequence of events now brings us to the discovery of the achromatic telescope. The first person who succeeded in making achromatic refracting telescopes seems to have been Chester Moor Hall, of Essex, Eng. He argued that the different humours of the human eye so refract rays of light as to produce an image on the retina which is free from colour, and he reasonably concluded that it might be possible to produce a like result by combining lenses composed of different refracting media. After devoting some time to the inquiry he found that by combining lenses formed of different kinds of glass the effect of the unequal refrangibility of light was corrected, and in 1733 he succeeded in constructing telescopes which exhibited objects free from colour. The principal development of the achromatic refractor is due to John Dollond who invented it independently (*Phil. Trans.*, 1758). In principle his object glasses were of the pattern mainly used at the present day, viz., convex lens of crown glass combined with a concave lens of flint glass. The concave lens is of less power than the convex, so that the combination converges the light as a single convex lens would do, but the flint glass, having much wider difference of refractive index for light of different colours, is able to correct the colour dispersion introduced by the more powerful crown lens. A triple objective, consisting of two convex lenses of crown glass with a concave lens of flint glass between them, was introduced in 1765 by Peter, son of John Dollond. This type is also employed in some modern telescopes. The difficulty of making large transparent and homogeneous disks of glass at first limited the use of these achromatic lenses to small telescopes for terrestrial use.

**Later Improvements.**—Late in the 18th century William Herschel greatly advanced the art of making mirrors of speculum metal, a hard brittle alloy having a composition of one part tin and two parts copper and a reflectivity of about 60%. Herschel's telescopes were much in demand for they were of better quality

FIG. 2.—DIAGRAM SHOWING COURSE OF RAYS WHEN THE EYE LENS IS CONVEX (OR POSITIVE)

and larger than any previously made. His two most famous telescopes were the 20-ft. of 19-in. aperture and the great 40-ft. of 48-in. aperture completed in 1789. The next step in the improvement of the reflector was made by Lord Rosse who built a series of telescopes culminating in the Parsonstown reflector of 72-in. aperture in 1845. The refracting telescope was brought back into favour in the first quarter of the 19th century after Joseph von Fraunhofer, who had learned from the younger Guinand how to make glass, succeeded in casting several disks of glass of excellent quality and in making lenses from them, computing the curves himself. The desire for greater magnification and light-gathering power led to the construction of lenses of larger and larger aperture. The U.S. optician Alvan Clark was especially successful in figuring large lenses and produced a long series of instruments culminating in the 36-in. of the Lick observatory and the 40-in. of the Yerkes observatory, which was completed in 1897. Disks of optical

glass of so great a size, free from strain, striations, veins and bubbles and other troublesome defects, are extremely difficult to cast and anneal. The great thickness of glass required for these large lenses absorbs an appreciable fraction of the light and reduces their effectiveness as light collectors. These and other reasons resulting from the shift in observing techniques discussed below caused a change back to reflectors early in the 20th century.

In the meantime many of the disadvantages of the speculum metal mirrors had been eliminated by the development of the silver-on-glass mirror. The discovery of a simple process by which a thin film of silver could be deposited on a glass surface was made by Justus von Liebig; the application of this discovery to glass mirrors and the methods of making and testing such mirrors was carried out by Jean Foucault in the 1860s. A freshly prepared silver film has a high reflectivity exceeding 90% throughout the visual spectrum. For wave lengths shorter than the blue the reflectivity falls at first slowly and then rapidly to a value of about 4% in the ultraviolet at 3,200 Å.

In the 1930s a process was developed by John Strong for coating glass mirrors with a film of aluminum by a vacuum distillation process. On exposure to the air the surface of the aluminum film rapidly oxidizes, giving a hard and durable reflecting layer. The reflectivity of the aluminum film is nearly as high as that of a freshly deposited silver film in the visual and does not have the large drop in reflectivity in the ultraviolet. The aluminum film deteriorates much less rapidly than the silver, requiring replacement every five or ten years while the silver must be renewed every few months. With these advantages aluminum almost completely replaced silver for coating large astronomical mirrors.

In order that the mirror shall not bend under its own weight and destroy the precision of the optical surface the glass disk must be very thick, usually about one-eighth of its diameter. Furthermore, to reduce the distortion of the mirror by changes in temperature, the present practice is to use mirrors of fused quartz or of a glass, such as Pyrex, that has a low coefficient of thermal expansion. The disk is ground to the rough shape required and then figured to the exact paraboloid or other surface specified. Since the final figure must not depart from the theoretical surface by more than a very few millionths of an inch this is a long slow

process; short periods of polishing being interspersed with careful optical tests to determine where the next polishing should be done and how much glass should be removed at each point.

After a precise surface has been achieved a layer of silver or aluminum is deposited to complete the mirror. The layer of metal is so thin that it does not affect the accuracy of the surface. When the surface tarnishes, the old film can be removed chemically and a new film deposited without injuring the figure of the glass.

## THEORY OF THE TELESCOPE

**Magnifying Power.**—The telescope consists essentially of two parts, the objective and the eyepiece. The light first passes the objective which forms an image, similar to that appearing on the ground glass of a camera. In small terrestrial telescopes the objective is an achromatic lens; in astronomical telescopes it may be either a lens or a concave mirror. The eyepiece is a short focus lens, like a small hand magnifier, which is used to look at and magnify the image formed by the objective. The magnifying power of a telescope is equal to the focal length of the objective divided by that of the eyepiece.

**Image Brightness.**—In addition to the magnifying power other factors that determine the performance of a telescope are image brightness, resolving power and field of view. In general a beam of light whose diameter is equal to that of the objective enters the telescope. The diameter of the beam leaving the telescope and entering the eye is equal to the objective diameter divided by the magnification. If the diameter of this beam, or emergent pencil as it is called, is greater than the diameter of the pupil of the eye, part of the light fails to enter the eye and is wasted. On the other hand, if the emergent pencil is much smaller than the pupil of the eye the apparent brightness of the image will be much lower than that of the object and the image will appear dark and indistinct.

The diameter of the pupil of the eye, however, varies through a large range depending on the illumination. Thus in full daylight the diameter of the pupil is 1.5 to 2 mm. while in darkness it expands to 8 or 10 mm. It is for this reason that telescopes designed primarily for nighttime observations have an exit pupil

of at least 7 mm.; e.g., the 50-mm., 7-power binocular used widely by the U.S. navy. An objective aperture of about one-fourth this would be adequate for daytime observation with the same power. In many general-purpose binoculars, however, a compromise emergent pencil of 3 to 5 mm. diameter is used as in the case of the 6- or 8-power glass with a 25- or 30-mm. objective.

**Resolving Power.**—The resolving power of a telescope is defined as the inverse of the smallest angle by which two points must be separated in order that they appear double in the telescope. From the wave theory of light it can easily be proved that the resolving power is proportional to the aperture of the telescope divided by the wave length of the light. If the magnification is increased to too high a value relative to the aperture of the objective the object appears blurred and no additional details can be detected. In general, no gain in observable detail is achieved by pushing magnification appreciably higher than the aperture of the objective expressed in millimetres.

**Field of View.**—The field of view of a telescope is defined as the angular diameter of an object that just fills the field that can be seen at one time. The apparent field of view is the angle subtended by the image of this object at the eye and is equal to the field of view times the magnification. The size of this apparent field of view is fixed primarily by the design of the eyepiece. The negative lens used as an eyepiece in the Galilean telescope gives a very small apparent field, ranging from  $30^\circ$  in a low-power opera glass to  $5^\circ$  in a telescope of high power. For this reason this type of eyepiece is used only in very low-power opera glasses and in cheap field glasses. The eyepiece consisting of a single positive lens suggested by Kepler yields a larger field but the definition is poor except at the centre of the field.

The first important improvement in eyepieces was made by Huygens, who introduced a design having two lenses separated by a distance equal to the average focal length of the component lenses. The Huygenian eyepiece, which gives an apparent field of about  $45^\circ$ , is still used, especially for the lower powers. The best instruments of the 20th century use the orthoscopic eyepiece, which consists of four lenses cemented in two groups and which yields critical definition even in the higher powers over an apparent field of  $40^\circ$  to  $50^\circ$ . Wide-field binoculars and some military instruments use the Erfle eyepiece, which consists of up to six glass elements and yields an apparent field of  $65^\circ$  to  $70^\circ$ .

**Erectness of the Image.**—For terrestrial observations the question of the erectness of the image must be considered. The negative eyepiece of the Galilean telescope yields an erect image. All of the other eyepieces mentioned above give inverted images if used alone with the objective. Erection of the image may be attained for the other types of eyepiece by the introduction of a third lens system between the objective and the eyepiece. This is the procedure used in the common draw tube telescope, although the introduction of the additional lens limits somewhat the field of good definition. The best instruments erect the image with two erecting prisms commonly of the Porro type (see BINOCULAR INSTRUMENT). This type permits the effective use of even the wide-angle Erfle eyepiece mentioned above.

### ASTRONOMICAL TELESCOPES

**Photographic and Photoelectric Observation.**—By the end of the 19th century the photographic plate had been developed to the point that it had many advantages over the eye for astronomical observations. The first of these is greater sensitivity for the study of faint objects such as nebulae or galaxies. Thus the photographic plate records fainter and fainter objects the longer it is exposed, while the eye sees nothing additional after the first glance. A few minutes exposure of the plate records everything the eye can see with the same instrument but the exposure may be continued for hours. No eye has ever seen the detail recorded on most astronomical photographs of nebulae, galaxies and other faint objects.

A second advantage of the photograph is the permanent record which it provides and which may be studied at leisure in the laboratory. The information recorded on a single plate may require months of measurement to evaluate. Such a photograph is often

of value years later to determine the initial state of a star that afterward explodes into a nova, or to locate the position of a planet that later calculations show passed the region covered by the plate at the time of its exposure.

Finally, modern photographic plates are sensitive to a much wider range of wave lengths than the eye.

Many other astronomical problems require the precise measurement of the brightness of an object with a photoelectric photometer or the analysis of its light with a spectrograph. For this purpose the objective of the telescope is used like a condensing lens or burning glass to concentrate the light of a star or other object on the aperture of the photometer or slit of the spectrograph.

Because of these developments visual observations are practically never made with the large modern telescopes used for fundamental research in astronomy. Strictly speaking these instruments are not telescopes at all but cameras or light-condensing systems. Most such telescopes have provision for the insertion of an eyepiece in place of the plateholder and this is occasionally done to view the field and make certain the telescope is pointed at the desired object before starting a long exposure. Another eyepiece is often mounted beside the plateholder to observe a guide star just outside the field being photographed. This is checked from time to time during the exposure and the position of the telescope adjusted to compensate for slight errors in the telescope drive. However, since practically all actual observations are made photographically or photoelectrically the telescopes are designed to give them maximum effectiveness as cameras or light condensers rather than as visual telescopes.

FIG. 3-5.—(3) PRIME FOCUS AND NEWTONIAN TELESCOPE; (4) CASSEGRAIN TELESCOPE; (5) COUDÉ TELESCOPE

See PHOTOGRAPHY, CELESTIAL; PHOTOMETRY, CELESTIAL; SPECTROSCOPY, ASTRONOMICAL.)

**Change in Design.**—This shift in the method of observation early in the 20th century resulted in a radical change in telescope design. The photography of very faint objects requires an objective of great speed, that is, one with a large ratio of aperture to focal length,  $f$ . Many problems require achromatism for the full range of plate sensitivity from the ultraviolet to the infrared. The two-lens objective of the 19th-century telescope with its lack of achromatism except for a narrow range of wave lengths in the visual and its aperture of  $f/15$  to  $f/20$  is quite inadequate for this method of observation. The concave paraboloidal mirror, however, is completely achromatic and gives optical definition at apertures as large as  $f/3$ . As a result practically all large telescopes constructed after 1900 were of the reflector type using concave mirrors with apertures between  $f/3$  and  $f/6$ . (See fig. 3-5.)

The reflecting telescope introduced several new problems of design. Thus a concave mirror (AA in fig. 3-5) focuses the image at a point (F) in the centre of the incoming beam of light. This is usually known as the prime focus. Except in the largest telescopes an observer placed at this focus to load plates and manipulate the telescope would obstruct too much incoming light. Most reflecting telescopes, therefore, have a small  $45^\circ$  plane mirror (BB in fig. 3) mounted at a short distance inside the focus to reflect the image to a point just outside the incoming beam. Since this arrangement was first proposed by Newton, this is known as the Newtonian focus.

For some purposes a longer focal length and therefore smaller ratio of aperture to focal length may be desirable. This is obtained by placing slightly inside the focus a convex mirror (BB in fig. 4) which reflects the light back through a hole in the centre of the main mirror and forms the image just behind this mirror. Because of the telephoto effect of this convex mirror, the focal length is increased by a factor of 3 to 8, and the ratio of aperture to focal length is decreased by the same factor. From the inventor of this arrangement the focus is known as the Cassegrain focus.

Finally in the coudé (French, "elbow") arrangement the light from a Cassegrain mirror is reflected down the polar axis by one or more plane mirrors (BB, CC and DD in fig. 5). In this case the focus, usually a short distance below the south polar bearing, remains fixed as the telescope is turned toward various parts of the sky. This arrangement can therefore be used to condense light on the slit of a spectrograph or other instrument too large to be mounted on the telescope.

**Wide-Field Cameras.**—For many investigations it is necessary to photograph large areas of the sky at one exposure. This requires

COURTESY OF R. W. PORTER AND THE CALIFORNIA INSTITUTE OF TECHNOLOGY

SECTIONAL DRAWING OF THE 200-IN. HALE TELESCOPE SHOWS THE TELESCOPE CUT AWAY ALONG A VERTICAL PLANE THROUGH THE POLAR AXIS

a field of good definition much larger than that provided by the simple achromat of the refracting telescope or by the paraboloidal reflector, especially when this is used at the low focal ratios needed for the photography of faint objects. For these studies complicated three- or four-lens systems, very similar to the anastigmat lenses for ordinary photography, were originally designed. These have been constructed with apertures up to 20 in.

In 1931 Bernhard Schmidt of the Hamburg observatory, Bergedorf, Ger., invented an entirely new optical system for use as a wide-angle camera. It consists of a concave spherical mirror and a thin correcting plate placed at the centre of curvature of the mirror. The very superior corrections of this system compared with that of any lens system made it possible to construct wide-angle cameras operating at apertures greater than  $f/1$ . Others have been constructed with an aperture as great as 53 in. The chief problem in the manufacture of the Schmidt camera is the corrector plate that has to be hand figured to a complicated fourth degree curve which is much more difficult than the spherical surfaces of the ordinary lens.

**Mounting.**—The mirror and photographic plate, spectrograph or photometer must be mounted on a structure that can be pointed

COURTESY OF (TOP, RIGHT) MT. WILSON AND PALOMAR OBSERVATORIES, (BOTTOM LEFT) LICK OBSERVATORY, (BOTTOM RIGHT) U.S. NAVY

(Top) 200-in. Hale reflector telescope and (right) 48-in. Schmidt telescope, Palomar and Mt. Wilson observatories, California; (bottom left) 20-in. astrographic telescope, Lick Observatory, California; (bottom right) 26-in. refractor telescope, U.S. Naval Observatory, Washington, D.C.

to objects at any place in the sky. This structure must also be provided with a drive mechanism so that once pointed at an object, the telescope can be turned to follow the object as it moves across the sky from east to west because of the earth's rotation. In order that no blurring of the image occurs it is necessary that this structure be very rigid so that it does not deform as it changes direction during an exposure of many minutes or even hours.

In typical mountings designed for modern telescopes, the main mirror is mounted at the lower end of the structure while for direct photography the plate is placed at either the prime or Newtonian focus near the upper end. In the Cassegrain or coudé arrangements the convex mirror is at the upper end.

In general, a structure can be pointed in all directions if two mutually perpendicular axes of rotation are provided. In very small visual telescopes these axes are often made vertical and horizontal in what is known as an altazimuth mount. For telescopes that are to be driven to follow the object across the sky, the equatorial mount is used. In this mount one of the axes, known as the polar axis, is made accurately parallel to the axis of the earth. The axis perpendicular to this is known as the declination axis. This type of mounting has the great advantage that any object can be followed from east to west by driving the polar axis at the uniform rate of one revolution in 24 hours.

Three different types of equatorial mounting were developed. (1) The English off-axis mount in which the polar axis is a relatively small tube with two bearings, one at the north and the other at the south. The telescope tube is mounted on one side with a counterweight on the other side of this polar axis. (2) The fork type has the telescope mounted between the tines of a fork projecting out from the two polar axis bearings both of which are at the south. (3) The yoke mounting holds the telescope tube symmetrically in a yoke, the polar axis bearings of which are at the

north and south. This type provides the most rigid support for the telescope and is therefore used for the largest instruments. Its disadvantage is that either the telescope cannot be pointed to the north pole or the north bearing must be made so large that the telescope can be turned down into it.

**The Hale 200-in. Telescope at Palomar Observatory.**—As of the 1960s the largest telescope constructed was the 200-in. Hale reflector on Palomar mountain in California. The main mirror is 200 in. in diameter and 24 in. thick and is ground and figured to give a focal length of 55 ft. To reduce thermal distortion during temperature changes it was cast from Pyrex glass with a ribbed structure and when finished weighed  $14\frac{1}{2}$  tons. In order to avoid flexure as the mirror is turned into different directions it is floated on 36 elaborate lever support systems each of which applies a force to the mirror just sufficient to compensate for the pull of gravity on the section of the mirror assigned to it. The mirror and its support system are mounted at the bottom of the telescope tube which is a rigid girder structure about 60 ft. long and with the mirror weighs 140 tons. At the centre of the upper end of the telescope tube is the prime focus cage in which provi-

sion is made for mounting the plateholder, photometers and small spectrographs. While observing at this focus the astronomer rides in the cage, six feet in diameter, which provides ample working space but intercepts only 13% of the light approaching the main mirror. Immediately below the observer's cage is a second cage in which are mounted the various secondary mirrors for the Cassegrain and coudé arrangements. When needed these mirrors are tipped forward into operating position by remote control.

The telescope tube is mounted between the arms of a yoke on declination bearings which permit the telescope to turn in a north-south direction. The yoke in turn is supported at both the north and south ends on the polar axis bearings which allow rotation of both telescope tube and yoke about an axis parallel to the earth's axis. The north polar bearing is made in the shape of an open horseshoe, the outer bearing surface having a diameter of 46 ft. This allows the upper end of the telescope tube to turn down to the centre of the bearing and thereby point at the north pole. The total weight of the telescope tube and yoke which turns about the polar axis is over 500 tons. North and south bearings are pressure-oil-pad types and have so low a friction that a  $\frac{1}{2}$ -h.p. motor is sufficient to drive the telescope when following a star.

At the Cassegrain focus the focal length is 267 ft. and at the coudé focus it is 500 ft. In addition to the photoelectric photometers and small dispersion spectrograph for use at the prime focus, a large spectrograph is available for use at the coudé focus. This has a collimator of 30-ft. focal length and five Schmidt cameras of aperture 12 in. and focal lengths from 8 in. to 12 ft.

The telescope is housed in a dome 135 ft. high and 137 ft. in diameter. The dome is rotated with a drive which automatically keeps the shutter opening in the dome lined up with the telescope at all times. The rotating part of the dome weighs 1,000 tons. (See also OBSERVATORY [ASTRONOMICAL].)

**Large Telescopes.**—The largest telescopes in operation in the mid-1960s are listed in the table. They are all reflectors, since no refractor with an aperture greater than 30 in. was built after the 19th century.

Large Telescopes

Name	Location	Aperture (in inches)	Focal length of primary	Date completed
Hale . . .	Palomar Mtn., Calif.	200	660	1948
Lock . . .	Mt. Hamilton, Calif.	120	600	1959
Crimean . . .	Crimea, U.S.S.R.	102	395	1960
Hooker . . .	Mt. Wilson, Calif.	100	508	1917
Kitt Peak . . .	Kitt Peak, Ariz.	84	220	1963
McDonald . . .	Mt. Locke, Tex.	82	324	1939
Haute Provence . . .	St. Michel, France	74	385	1958

**TELESCOPE, RADIO.** Radio waves arriving at the earth from the solar system, the galaxy, and the extragalactic nebulae are a source of remarkable information about the universe (see RADIO ASTRONOMY). No less remarkable are the huge and delicate radio telescopes invented to extract this information from the minute quantities of energy that these distant objects send us.

**Steerable Paraboloids.**—Observations in radio astronomy are carried out with various kinds of radio telescope, of which the best known resemble the 250-ft. (76-m.) diameter reflector erected at Jodrell Bank, Eng. Grote Reber made the first radio maps of our galaxy in 1942 with such a reflector. This kind of radio telescope, the steerable paraboloid, functions as shown in fig. 1. Radio waves from a distant astronomical source S fall on the curved surface, which, being made of a good electrical conductor, causes the waves to be reflected in accordance with Snell's law; thus the ray incident at R is reflected in the direction RF. If the reflecting surface is correctly curved, all the reflected rays can be made to arrive at the same focus F. The curve that accomplishes this is the parabola; consequently, the correct shape for the reflecting surface is a paraboloid. The downcoming energy is spread thinly over the extensive circular aperture, but the focusing property causes it to converge on the radio receiver; it is detected at the receiver if the amount of energy passing through the circle C that forms the rim of the reflector is sufficiently large to be detectable.

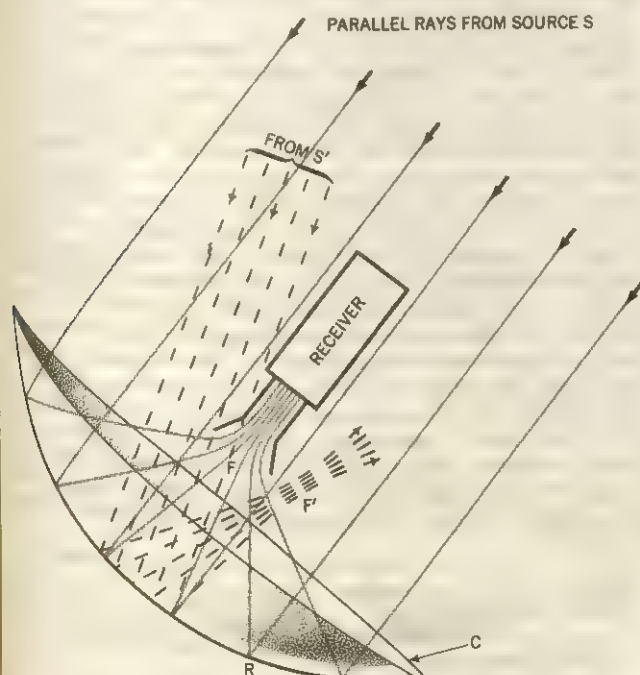

FIG. 1.—STEERABLE PARABOLOID

At the focus F is placed an electromagnetic horn that "swallows" the converging energy and pipes it through a hollow wave guide to the receiver. At lower frequencies dipoles connected to electrical transmission lines are used in place of horns. For successful action the aperture of the horn must be about equal in extent to the radio wavelength, because that is the least compass into which the converging waves can be condensed.

A source S', not in exactly the same direction as the source S, sends its energy toward a point F', which is off to the side of the collecting horn; if it is too far to the side, it fails to be collected and passes back into space. The paraboloid antenna thus has the ability to receive from a narrow cone of directions around S and to ignore other directions. This property of directivity is important in discriminating one source from another and in discerning fine detail in such sources as the sun, where it is necessary to be able to examine small areas around sunspots without intercepting radiation from other parts of the sun. It is customary to describe this property of the antenna by its beamwidth, which is the angle between directions from which only half the full power is received. Bearing in mind that the size of the focal area increases as the wavelength increases, it will be seen from fig. 1 that the larger the antenna the narrower the beamwidth, provided the wavelength remains fixed, and conversely that if the size of the antenna is kept fixed, then the shorter the wavelength the narrower the beamwidth. Beamwidths for some representative sizes of antennas are listed in Table I. The beamwidth, which is shown in degrees and minutes of arc, refers to an ideal antenna that is precisely of

TABLE I.—Beamwidths of Various Antenna Sizes

Diameter of antenna	Wavelengths			
	3 cm.	10 cm.	30 cm.	3 m.
60 ft. . . .	7'	23'	1°10'	11°40'
140 ft. . . .	3'	10'	30'	5°
210 ft. . . .	2'	7'	20'	3°20'

paraboloidal shape. In practice, however, the surface will depart from the true paraboloid for such reasons as manufacturing tolerances, the force of the wind, uneven expansion and contraction of the structure, and sagging of the parts under their own weight. As a consequence, an actual antenna does not focus as well as a true paraboloid would; some of the focused energy thus fails to be collected by the horn. The ability of the antenna to receive energy is expressed in terms of its effective area, which equals the area of a perfect absorber intercepting as much energy as is collected at the focus of the actual antenna and delivered to the receiver. The effective area is typically about 60% of the actual aperture. Each antenna has a wavelength limit beyond which its performance is seriously impaired by imperfect focusing.

The way in which the effective area A deteriorates as the wavelength decreases is expressed by the equation

$$A = \frac{\mathcal{D}^2}{\lambda^2 + 2\pi\mathcal{D}Q} \times \pi R^2$$

where R is the radius of the circular rim of the paraboloid,  $\mathcal{D}$  is the factor by which the effective area would fall below the physical area  $\pi R^2$  even if the reflector were perfectly paraboloidal, and  $\lambda$  is the wavelength. The quantity Q measures the imperfection of shape. If we suppose that waves are radiated by the antenna from a source at the focus, then the wave fronts emerging from the aperture are plane, but if there is a bump on the reflector, then there will be a bump, almost twice as high, on the emerging wave front; Q is the mean square departure of this wave front from the plane of best fit.

Not all radio telescopes have a parabolic reflector, and, indeed, any type of radio antenna is usable. Every radio telescope, however, comprises an antenna, a receiver, an output indicator, and a means of pointing the beam in known directions (fig. 2).

The receiver may assume various forms; for example, it may consist simply of an amplifier, a detector, a direct-current amplifier, and a filter for smoothing the fluctuations. The output indicator is essentially a meter, usually a recording milliammeter giving a permanent record on a paper chart. In addition, how-

FIG. 2.—BASIC COMPONENTS OF A RADIO TELESCOPE

ever, the observational results will be recorded on punched cards or magnetic tape if they are to be fed to a computer for numerical analysis, or typed out on an automatic typewriter if the output is in final form suitable for publication.

To point the beam of a radio telescope, one simply mounts the antenna suitably and with the aid of drive motors and position indicators drives the antenna to the desired position. In sizes up to about 100 ft. it is convenient to use an equatorial mount, in which one axis of rotation is parallel to the earth's axis; then in order to follow a radio source as it moves across the sky, it is sufficient to compensate for the earth's rotation by driving the antenna westward about its own polar axis. The larger antennas use altazimuth mounts, which are cheaper to build to the requisite strength, and it is necessary to drive such antennas both in altitude and azimuth to follow a source. Since the drive motors are called on to vary their speed in a precisely defined way, a computer is required to control an altazimuth drive system.

Mechanically steered paraboloids, such as those described above, represent only one type of radio telescope. Typical examples of such steerable paraboloids are listed in Table II.

TABLE II.—Some Mechanically Steered Paraboloids

Diameter (ft.)	Location	Mount	Wavelength limit
250	Jodrell Bank, Eng.	altazimuth	21 cm.
210	Parkees, New South Wales, Austr.	altazimuth	5 cm.
150	Stanford, Calif.	altazimuth	50 cm.
140	Green Bank, W. Va.	equatorial	2 cm.
120	Haystack Hill, Mass.	altazimuth	2 cm.

For many purposes the large steerable paraboloids have not been large enough, and various more sophisticated antennas have been developed. To understand why the demand for greater effective area cannot be met by enlarging the simple steerable paraboloid, imagine an antenna 500 ft. in diameter all of whose dimensions are precisely twice those of a certain 250-ft. antenna. The larger antenna will require eight times as much steel but will provide only four times as much collecting area. Moreover, under the increased weight, the structural members, which must be twice as long as in the 250-ft. antenna, will sag away from the true paraboloid by four times as much as before, so that even more steel will have to be added to stiffen the structure. It is clear that the cost per square metre of collecting area is higher for the larger antenna. This explains why radio astronomers have often been able to accomplish more for a given capital outlay by adopting other antenna designs.

**Fixed Reflectors.**—Much more effective area can be obtained for the same cost if the reflector does not have to be movable. An example is furnished by the 1,000-ft. spherical reflector built by W. E. Gordon of Cornell University at Arecibo, P.R. (fig. 3A). Each zone of a spherical reflector possesses a focus; for example, the outermost zone AB has its focus at R, and the zone CD has its focus at Q. The energy coming from the source S directly overhead converges on the line PR, where a special collector can be placed. If this collector is rotated about the centre of the sphere to position P'R' as in fig. 3B, it is in the correct position to receive energy from the source S'. Thus the beam of the antenna has been pointed away from the zenith without the reflector having been moved.

Another example of a fixed reflector is the 600- × 400-ft. parabolic cylinder constructed by G. W. Swenson at the Vermilion River Observatory in Illinois (fig. 3C). Downcoming energy

comes to a line focus FG, which is occupied by a large number of small antennas connected by transmission lines to a receiver. This radio telescope receives signals only from sources on the meridian, but the altitude of the beam can be varied by adjusting the electrical phase of each focal antenna.

In still another design (J. D. Kraus of Ohio State University) a tiltable flat reflector T (fig. 3D) reflects incoming rays from directly overhead into the horizontal direction toward a fixed reflector R, which is a zone of a paraboloid with its focus at F. A similar large radio telescope was built by J. F. Denisse at Nançay, France.

FIG. 3.—FIXED REFLECTORS

**Interferometers.**—The most pressing problem at the time of the discovery of the radio sources was to ascertain the precise locations of the sources and their angular diameters. Had very large parabolic reflectors been available, they would have accomplished this aim; because they were not, the answers were obtained with modest antennas deployed as interferometers. In the subsequent development of radio telescopes, interferometers have maintained their important role, especially in new discoveries, essentially because of their ability to furnish better angular resolution than a parabolic reflector of the same cost.

A two-element interferometer is an antenna consisting of two well-spaced components connected by transmission lines to a receiver. Instead of transmission lines a radio link may be used and preamplifiers may be introduced to offset transmission losses; hence the electronic parts may be distributed throughout the system and not confined to the central receiver. Fig. 4 shows an interferometer with dipoles D at the foci of two reflectors connected by two-wire transmission lines L to a receiver. The record shows the response to two discrete sources passing successively through the beam of the interferometer. The maxima and minima are due to interference between the voltages transmitted to the receiver by the two antennas; the maxima occur when the path difference is a whole number of wavelengths and the two voltages arrive at the receiver in the same phase. The minima occur when the voltages are opposed in phase. It will be seen from the minimum  $N_1$  that the two opposing voltages canceled out to zero, which is typical of a point source; the maximum  $X_1$  is twice what would be obtained with a single antenna. By analogy with interference in optics these peaks of response are called fringes. The less pronounced fringes of the second source reveal that it has an

FIG. 4.—INTERFEROMETER

FIG. 5.—CROSS ANTENNA, STANFORD, CALIF.

angular extent that is an appreciable fraction of the angle between fringes, because when the radiation from the centre of the source cancels out at the receiver, the radiation from the edges does not cancel out.

When the antennas are  $n$  wavelengths apart on an east-west line and are pointed at the meridian, the fringe separation is one  $n$ th of a radian; e.g., with a spacing of 1,000 wavelengths the fringe separation is 0.001 radians or 0.057°. Such an instrument allows source diameters of about one minute of arc to be determined, which would be well beyond the capability of the component antennas taken singly. This interferometer also permits the source position to be pinpointed to about a minute of arc in right ascension.

To do as well with a single antenna would require one about 1,000 wavelengths long, which would be much more costly. The extra cost would, however, buy a larger effective area, which, under most circumstances, would be highly valuable.

The mapping of complex sources can also be accomplished by interferometry. For this purpose observations must be made with a range of antenna spacings. One plan, which has been highly developed in England by M. Ryle, is to move the antennas bodily; another is to construct several antennas in fixed locations; e.g., in a cross.

**Cross Antennas.**—An example of a cross is shown in fig. 5, where two arrays of equatorially mounted antennas, all driven in unison, are shown arranged in a cross. The cross arrangement was first demonstrated by B. Y. Mills in Sydney, Austr., with long fixed arrays of metre-wave dipoles, but the cross in fig. 5 is an adaptation to steerable microwave reflectors. The voltages, delivered to the centre by the two arms, are multiplied together, and the product, which is instantaneously printed by an automatic typewriter, gives the brightness temperature of the sun. The fine beam of the instrument is able to single out a patch of the sun amounting to only 1% of the surface at a time and is capable of scanning the entire sun to build up a meteorological map by means of isotherms.

Crosses may be very large. The Mills cross of the University of Sydney, for example, has arms one mile long, and similar instruments constructed in the Soviet Union by V. V. Vitkevich and in Italy by M. Ceccarelli have arms one kilometer long. Details of some of these instruments are shown in Table III.

**BIBLIOGRAPHY.**—Complete issues of the following periodicals are devoted largely to radio telescopes: *Proceedings of the Institute of Radio Engineers*, vol. 46 (Jan. 1958); *IRE Transactions on Antennas and Propagation*, vol. AP-9 (Jan. 1961); *Proceedings of the Institution of Radio Engineers Australia*, vol. 24 (Feb. 1963). For photographs of many radio telescopes and technical discussions, see J. L. Steinberg

and J. Lequeux, *Radio Astronomy* (1963) and R. N. Bracewell, "Radio Astronomy Techniques" in *Encyclopaedia of Physics*, vol. 54 (1961). (R. N. BL.)

**TELESIO, BERNARDINO** (1509–1588), Italian philosopher and scientist, inaugurated empiricist reaction against the authority of abstract reason as represented by scholastic Aristotelianism. He was born of noble parentage at Cosenza, in the Kingdom of Naples, where he was later to add lustre to the circle of thinkers known as the Accademia Cosentina. After studies (1518–35) in Milan, Rome, and Padua, he spent about nine years in a monastery. Thereafter he lived mainly in Naples (1545–52 and 1563–87) or at Cosenza, where he died.

The first two books of Telesio's *De rerum natura iuxta propria principia* ("On the Nature of Things According to Their Own Principles") appeared in 1565, the complete work, in nine books, in 1586 (modern edition by V. Spampinato, 1910–23). He also published three subsidiary essays on physical science in 1570 and left others, some of which were printed in 1590. Contemporary popes had encouraged him, and he saw nothing anti-Catholic in his doctrine; but from 1596 to 1900 the *De rerum natura* and two minor works were on the Index "pending correction."

Discarding Aristotelian physics, Telesio proposed an inquiry into the data of the senses, from which he held all human knowledge to be derived. He argued for two incorporeal first principles, heat and cold, acting on the inert matter of the earth: from the varying degrees of this action's intensity all the diverse types of existence result. In his psychology and ethics, there is no clear qualitative distinction between animal and human faculties, nor between the physiological and the spiritual. Defects in his system were pointed out by his pupil Francesco Patrizzi, whose objections he tried to meet; but he set the example of independent investigation that Tommaso Campanella and others were soon to follow.

## I. INTRODUCTION

The purpose of a television system is to extend the senses of vision and hearing beyond their natural limits. Television systems are designed, therefore, to embrace the essential capabilities of these senses, with appropriate compromises between the quality of the reproduction and the costs involved. The aspects of natural vision which must be considered in a television system include the ability of the human eye to distinguish the brightnesses, colours, details, sizes, shapes and positions of the objects in the scene before it. The aspects of hearing include the ability of the ear to distinguish the pitch, loudness and distribution of sounds. The television system must also be designed to override, within reasonable limits, the effects of interference and to minimize visual and aural distortions in the transmission and reproduction processes. The particular compromises adopted for public television service, *i.e.*, by broadcast means, are embodied in the television standards adopted and enforced by the responsible government agency in each country.

Television technology must deal with the fact that human vision employs many hundreds of thousands of separate electrical circuits, in the optic nerve from the retina to the brain, to convey simultaneously in two dimensions the whole content of the scene on which the eye is focused, whereas in electrical communications it is feasible to employ only one such circuit (*i.e.*, the broadcast channel) to connect the transmitter and the receiver. This fundamental disparity is overcome in television by a process of image analysis and synthesis, whereby the scene to be televised is first translated into an electrical image, and the latter is then broken up into an orderly sequence of electrical impulses which are sent over the channel one after the other. At the receiver the impulses are translated back into a corresponding sequence of lights and shadows and these are reassembled in their correct positions on the viewing screen.

This sequential reproduction of visual images is feasible only because the visual sense displays persistence; that is, the brain retains the impression of illumination for about 0.1 sec. after the source of light is removed from the eye. If, therefore, the process of image synthesis occurs within less than 0.1 sec., the eye is unaware that the picture is being reassembled piecemeal, and the viewing screen appears as if its whole surface were continuously illuminated. By the same token, it is then possible to recreate more than ten complete pictures per second and to simulate thereby the motion of the scene.

In practice, to depict rapid motion smoothly, it is customary to transmit from 25 to 30 complete pictures per second. To provide detail sufficient to accommodate a wide range of subject matter, it is customary to analyze each picture into 100,000 or more elementary details. This implies that the rate at which these details are transmitted over the television system exceeds 2,000,000 per second. To provide a system suitable for public use and yet capable of such speed has required the full resources of modern electronic technology.

## II. HISTORY OF TELEVISION

The development of television was marked by an early appreciation of its basic concepts, followed by a delay of several dec-

ades in which apparatus was gradually improved to such a point that the principles could be demonstrated. The basic principle of translating light into its electrical counterpart was discovered in 1873 by an English telegrapher, L. May, who found that electrical resistance of the element selenium was substantially reduced under illumination. The photoconductive action of selenium is so sluggish that the early television systems could not use this phenomenon and it was not until 1950 that a photoconductive television camera tube, the Vidicon, was fully developed. W. Hallwachs in 1888 first demonstrated the photoelectric effect, by which electrons are emitted substantially instantaneously from an illuminated surface. This effect was first put to use in a crude television system in 1923, when J. L. Baird in England and C. F. Jenkins in the United States demonstrated the transmission of crude black-and-white silhouettes in motion. Baird and Jenkins were successful in 1925 in demonstrating electrically transmitted moving pictures in half tones, and this is generally conceded to be the start of television as an operational technology. But the televised pictures were so crude that they hardly qualified as an extension of the sense of sight, and it was not until 1936 that a public television service, capable of supporting a regular program of entertainment, was inaugurated in London by the British Broadcasting corporation.

The earliest proposals for television systems suggested that the action of the eye be imitated by setting up a mosaic of light-sensitive elements, as in the retina, with an individual telegraph circuit attached to each element, as in the optic nerve. The picture was to be reproduced by a similar mosaic of electrically operated shutters, actuated individually by the telegraph circuits. To secure a picture of detail equal to that of modern television by this method would require over 100,000 circuits between transmitter and receiver, an obviously impractical arrangement. The multiple-circuit mosaic system has never been demonstrated as a television system, although the principle has been used in animated electric signs to produce crude pictures in motion.

The concept of analyzing and synthesizing an image so that it could be transmitted over a single communication channel was first announced in 1884 in a German patent by P. Nipkow. Variations of Nipkow's scheme were used by Baird and Jenkins in 1923-25 and it deserves an important place in the history of television. As illustrated in fig. 1, the image to be televised is focused on a rotating disk with square apertures arranged in a spiral around its edge.

As the disk rotates, the outermost aperture traces out a line across the top of the image, and the light passing through the aperture varies in direct proportion to the light and shadows of that line of the image as they are sequentially uncovered by the aperture. When the outermost aperture has passed over the image, the next inner aperture traces out another line, parallel to and just below the line just traced. The changes in the light passing through the second aperture represent, in sequence, the lights and shadows present in the image along this second line. As the disk continues to rotate, successive lines are traced out, one beneath the other, until the whole area of the image has been covered, one line at a time.

In this way, the lights and shadows of the image are sequentially explored in an orderly manner. The light passing through the apertures enters a photoelectric cell which translates the sequence of light values into a corresponding sequence of electrical values. These are transmitted over a single electric circuit to the receiver.

At the receiver, the electrical impulses cause light to be produced by a lamp (such as a gas-discharge lamp) capable of reproducing the sequence of light values. The varying light from

FIG. 1.—NIPKOW DISK FOR AN IMAGE FIELD

the lamp is projected on the surface of a disk, similar to that at the transmitter. The receiver disk must rotate in precise synchronism with the disk at the transmitter, that is, the position of each aperture, relative to the light source, must at each instant of time be precisely the same as the position of the respective aperture of the transmitter disk relative to the scene to be transmitted. Thus, as the outermost aperture of the disk at the transmitter passes over the upper line of the scene, the corresponding aperture in the receiver disk allows light to pass to the observer, and the lights and shadows of the upper line in the image are thus recreated. As the disks continue to revolve in synchronism, the receiver reproduces, line by line, the same sequence of lights and shadows as are uncovered by the apertures of the transmitter disk. If the whole area of the image is covered within a few hundredths of a second, the persistence of vision of the observer comes into play and the full lengths of all the lines appear to be illuminated simultaneously. The eye thus sees an area of illumination, when viewing the receiver disk, although in point of fact light is emerging from only one aperture at a time. The receiver disk thus reassembles the lights and shadows of the transmitted sequence in their proper positions and the image is reproduced.

The process is repeated once during each rotation of the disks. If the disks rotate at, say, 30 revolutions per second, 30 complete still pictures are reproduced each second. Any motion in the image is thus broken up into increments of  $\frac{1}{30}$ -sec. duration. The succession of such small motions cannot be resolved by the eye, and the illusion of smooth motion is thus created. This principle of rapid, sequential exploration of light values and synchronous reassembly of corresponding light values underlies all modern television technology.

The Nipkow scheme and its many mechanical variants failed to provide a satisfactory television system because of the extraordinary demands of the sense of sight with respect to pictorial detail. To provide a pictorial setting for a wide variety of subject matter, the image must be capable of being analyzed into at least 100,000 (preferably 200,000) separate lights and shadows (picture elements). This means that the picture must be divided into several hundred lines (approximately the square root of the number of picture elements) and that each line must contain several hundred individually identifiable halftone light values. The Nipkow disk must then contain several hundred precisely located apertures, and the receiver light source must be capable of assuming several hundred different light values during the approximately 0.00005 sec. that is available for the tracing of each line. Neither requirement is beyond the limits of modern technology (a nonmechanical variant of the Nipkow system, the flying spot scanner, is in fact used in modern practice for film transmissions). The difficulty is that the light passing through each aperture of the Nipkow disk is then limited to roughly  $\frac{1}{100,000}$  of the total light present in the scene, and the scheme is therefore effective only when the scene is very brilliantly illuminated (as in sunlit outdoor scenes or in motion-picture projection apparatus). In modern television, mechanical image analysis has been replaced by electronic exploration of the lights and shadows of the image. Such electronic apparatus can operate at any required speed and, most important, it can "store" the effect of light so as to increase the sensitivity of the television camera by about 100,000 times.

The long delay between the Nipkow proposal and Baird and Jenkins' practical demonstrations was occasioned largely by the necessity of amplifying the weak electrical impulses produced by the photocell at the transmitter to a strength sufficient to operate the lamp at the receiver. The invention of the thermionic amplifier tube by Lee De Forest in 1907 provided the basic means, but substantial additional work was necessary to secure the high-speed amplification needed for even crude television transmissions.

For a decade after the first halftone transmissions in 1925, great effort was expended to produce images of fine detail from scenes under normal illumination, and experimental broadcasts were conducted by Baird, Jenkins, E. F. W. Alexanderson and others, using image analysis of 60 to 120 lines per picture at about 20

pictures per second. When public broadcasting began in London in 1936, one of the two systems used was a highly refined mechanical system developed by Baird, producing images of 240 lines at 24 pictures per second. But within a few months the mechanical methods were abandoned in favour of electronic analysis at 405 lines and 25 pictures per second, the values still in use in the British television system. Experimental broadcasting by the electronic method also began in New York in 1936, but officially authorized transmissions for the public did not begin in the United States until July 1941.

The conceptual base of the modern electronic television system was laid down in 1907 by a Russian, Boris Rosing, and an Englishman, A. A. Campbell-Swinton, who independently suggested the use of cathode rays (electron beams) for reconstitution of the image at the receiver. A cathode-ray tube had been developed as early as 1897 by K. F. Braun to trace curves on a phosphor surface.

In 1911 Campbell-Swinton proposed, for a television camera, the use of a photosensitive mosaic which would accumulate electric charge and be discharged by a moving cathode ray. This important concept, without which modern television could hardly exist, was not reduced to practice until 1925 when the American V. K. Zworykin (who had studied under Rosing) applied for his patent on the iconoscope. The iconoscope is still used in film telecasting and its lineal descendants, the orthicon and the image orthicon (see *Television Camera Tubes*, below), are used for nearly all telecasting of "live" subject matter.

Prior to 1932, experimental television transmissions were broadcast on frequencies near the standard sound broadcasting band, in the vicinity of two megacycles, since the crude 60-line picture transmissions of those days could be accommodated in channels not dissimilar to those used for sound broadcasting. In the early 1930s it became clear that much finer image detail was needed to support a program service, and at that time the electronic devices (iconoscope camera tube and cathode-ray picture tube) became available to produce higher definition in the pictures. It was then recognized that the two megacycle frequencies were not suited for the more refined methods of reproduction, and a wholly new region of the radio spectrum was explored for television. This region extends upward from about 50 mc. in the so-called very-high-frequency (VHF) band. By 1936 all activity on the two megacycle band had ceased in favour of the VHF channels, which provide the necessary channel space for transmission of highly detailed pictures. The VHF channels continue in use (extending from 54 to 216 mc., channels 2 through 13) and, in fact, form the backbone of television service throughout the world. Additional channels in the ultrahigh-frequency (UHF) band (from 470 to 890 mc., channels 14 through 83) were allocated to television broadcasting in the United States.

The period 1936-40 was marked in the United States by a vigorous debate on the precise form which public television service should take, particularly how detailed the pictures should be to support a wide variety of program fare. The first "all-electronic" system to be demonstrated in the U.S. transmitted pictures by radio relay between New York city and Camden, N.J., with one intermediate relay point at Arney's Mount, N.J. These pictures were analyzed into 240 lines and sent at 24 pictures per second. By 1934 the number of lines per picture had been raised to 343 and the picture rate to 30 per second. By 1940 an "industry standard" of 441-line pictures was suggested by the trade association of the radio industry and was used experimentally. Finally, in 1940, a committee of experts, the first National Television System committee (N.T.S.C.), recommended transmission at 525 lines per picture, 30 pictures per second. These values, with other specifications recommended by the N.T.S.C., were adopted by the Federal Communications commission in 1941 and subsequently served as the basis of U.S. television service. The only other national television standard then in use was the 405-line picture, sent at 25 pictures per second, of the British Isles. Shortly thereafter, transmissions at 441-lines began in Paris; after World War II this standard was raised to 819 lines. Beginning in 1949 a group of European countries, led by the Dutch and the Swiss, adopted standards generally patterned after the U.S. sys-

BY COURTESY OF THE NATIONAL BROADCASTING CORP.

Roosevelt, the first U.S. president to appear on television, photographed as he went before the cameras, 1939; (right) V. K. Zworykin, inventor of the iconoscope, by an early experimental set with a 5-in. screen, c. 1938

tem, with pictures analyzed into 625 lines, transmitted at a rate of 25 pictures per second. The latter standards are widely used, except in North America, most of South America and Japan, which adhered to the 525-line system.

When wartime restrictions governing the manufacture of receivers were removed in 1946, the stage was set in the U.S. for a rapid growth of the television broadcasting industry. By 1949 there were 1,000,000 receivers in use; the 10,000,000 mark was passed in 1951 and the 50,000,000 mark eight years later. About half that number were in use in the 50 other nations which by then had established regular program services. By the mid-1960s receivers in use throughout the world totaled about 149,000,000; about 62,600,000 were in the U.S. and 5,400,000 in Canada; Japan had 16,000,000, second only to the U.S.

The development of colour television paralleled that of the black-and-white variety. It was early appreciated that it was necessary to transmit and superimpose three images in the respective primary colours to achieve the desired result. A German patent issued in 1904 contained the earliest definitive proposal. Reduction to practise was delayed while the operative problems of monochrome television were being solved. The first demonstration of television in colour was offered by Baird in 1928, five years after his first monochrome demonstration. Mechanical scanning was used, with a Nipkow disk having three sets of apertures, one for each primary colour. In 1929 the first colour television demonstration in the U.S. was made by H. E. Ives and his colleagues, who transmitted 50-line colour images at about 18 pictures per second over wires between New York and Washington, D.C.

The subsequent refinement of the art to a form suitable for public colour program service took place in the United States, culminating in the compatible colour system introduced in 1954. Prior to this, mechanical colour television methods were brought to an advanced state by Peter Goldmark, who first demonstrated in 1940 in New York a mechanical system of televising images in full colour, with 343 lines per picture and complete sequential coverage of the image in three colours at a rate of 20 pictures per second.

Following the war, Goldmark further refined this system.

In 1949 he proposed to the Federal Communications commission that colour television be officially authorized with images of 405 lines, transmitted sequentially with three-colour coverage at a rate of 24 pictures per second.

In 1950 the commission adopted this recommendation and authorized transmissions under these standards began in New York in 1951. This colour system was incompatible with the then-existing monochrome service; that is, the 10,000,000 receivers then in the hands of the public could not reproduce the colour transmissions in monochrome. This fact, together with the limitations on design and manufacture imposed by the Korean war, forced abandonment of the sequential colour system late in 1951.

Meanwhile, the second National Television System committee was convened to study the means of transmitting colour television in compatible fashion. The basis of compatible colour television was laid down in 1948-49 by various workers in the U.S. television industry, and the task of the second N.T.S.C. was to develop and select the precise methods which would comprise the public service. The N.T.S.C. system was perfected in 1953 and recommended to the FCC in that year. Beginning in 1954, authorized public service began under standards identical to the N.T.S.C. recommendations. Subsequently, the N.T.S.C. system was the subject of study by European television engineers. The majority opinion was that the European colour service, when authorized, should follow the principles of the N.T.S.C. system.

The compatible colour system (*see below*) is a remarkable technical tour de force which, prior to 1946, would have been flatly rejected by experts as impossible of practical attainment. The basic principle is the combination of two image transmissions, one carrying the fine details in black and white (to which monochrome receivers respond), the other of coarser structure, carrying the colour information. This second component has no appreciable effect on monochrome sets. Colour receivers respond to it, in concert with the monochrome transmission. Since the ability of the eye to perceive detail is most acute when viewing white light, the black-and-white component of the colour image carries the impression of fine detail and the superimposed coarse colour information does not substantially alter the sharpness of the resulting colour picture.

Colour receivers are intrinsically more complicated than black-and-white receivers, and hence more expensive to purchase and maintain in good order. This fact, plus the fact that the essential content of the compatible colour programs is available (in monochrome) to owners of black-and-white receivers, delayed full acceptance of the colour service by the public. The technical basis of the compatible colour service is sound, however, and it seemed certain that the economic barriers would be removed with further development of receiver circuits and components.

### III. FUNDAMENTALS OF PICTURE TRANSMISSION AND RECEPTION

The quality and quantity of television service are limited fundamentally by the rate at which it is feasible to transmit the picture information over the television channel. As already noted, in modern practice the televised image must be capable of being dissected, within a few hundredths of a second, into more than 100,000 picture elements. This implies that the electrical impulses corresponding to the picture elements must pass through the channel at a rate as high as several million per second. Moreover, since the picture content may vary from simple close-up shots having little fine detail to comprehensive distant scenes in which the limiting detail of the system comes into play, the actual rate of transmitting the picture information varies from time to time, from a few impulses per second to several million per second. The television channel must be capable, therefore, of handling information over a continuous band of frequencies several million cycles wide. This is testimony to the extraordinary comprehension of the sense of sight. Hearing is comparatively crude. The ear is satisfied by impulses which can be carried over a channel only 10,000 cycles wide.

In the United States, the television channel occupies a width of 6 mc. (6,000,000 cycles per second) in the radio spectrum.

This is 600 times as wide as the channel used by each standard sound broadcasting station. In fact, each television station uses nearly six times as much spectrum space as all the commercial sound broadcasting channels combined. Since each television station must occupy so much spectrum space, few channels are available in a given locality. Moreover, the quantity of service is in conflict with the quality of reproduction. If the detail of the television image is to be increased, other parameters of the transmission being unchanged, the channel width must be increased proportionately, and this decreases the number of channels which can be accommodated in the spectrum. This fundamental conflict between quality of transmission and number of available channels dictates that the quality of reproduction shall just satisfy the typical viewer under the normal viewing conditions of the home. Any excess of performance beyond this would ultimately result in a restriction of program choice.

The first requirement to be met in image analysis is that the reproduced picture shall not flicker, since flicker induces severe visual fatigue. Flicker becomes more evident as the brightness of the picture increases. If flicker is to be unobjectionable at brightnesses suitable for home viewing during daylight as well as evening hours (25 to 100 foot-lamberts), the successive illuminations of the picture screen should occur not less than 50 times per second. This is approximately twice the rate of picture repetition needed for smooth reproduction of motion. To avoid flicker, therefore, twice as much channel space is needed as would suffice to depict motion. The same disparity occurs in motion-picture practice, in which satisfactory performance with respect to flicker would require twice as much film as would be necessary for smooth simulation of motion.

FIG. 2.—COMBINATION OF TWO SEPARATE SCANNING CYCLES (FIELDS) DURING EACH TRANSMISSION PERIOD PRODUCES COMPLETE PICTURE

A way around this difficulty has been found, in motion pictures as well as in television, by projecting each picture twice. In motion pictures, the projector interposes a shutter briefly between film and lens while a single frame of the film is being projected. In television, each image is analyzed and synthesized in two sets of spaced lines, one of which fits successively within the spaces of the other (fig. 2). Thus the picture area is illuminated twice during each complete picture transmission although each line in the image is present only once during that time. This technique is feasible because the eye is comparatively insensitive to flicker when the variation of light is confined to a small part of the field of view. Hence flicker of the individual lines is not evident. If the eye did not have this fortunate property, many towns possessing two television channels would have only one.

It is thus possible to avoid flicker and simulate rapid motion by a picture rate of about 25 per second, with two screen illuminations per picture. The precise value of the picture-repetition rate used in a given region has been chosen by reference to the electric power frequency which predominates in that region. In Europe, where 50-cycle power is the rule, the television picture rate is 25 per second (50 screen illuminations per second). In North America, the picture rate is 30 per second (60 screen illuminations per second) to match the 60-cycle power which predominates there.

A precise match between power frequency and the screen illumination rate is not necessary, and in fact seldom occurs over the area of an extensive network broadcast. A disparity of more than one or two cycles between the two values, however, would require additional costs in receivers to avoid picture distortion. The higher picture-transmission rate of North America allows the pictures there to be about five times as bright as those in Europe for the same susceptibility to flicker, but this advantage is offset by a 20% reduction in picture detail for equal utilization of the channel.

The second aspect of performance to be met in a television system is the detailed structure of the image. A printed halftone engraving may possess several million halftone dots per square foot of area. Such reproductions are intended for minute inspection and the dot structure must not be apparent to the unaided eye even at close range. Such fine detail would be a costly waste in television, since the television picture is viewed at comparatively long range (5 to 15 ft. in the typical home setting) and the picture area is not greater than 2 sq.ft. Under these conditions, a picture structure of about 200,000 halftone elements is a suitable compromise. This detail is about equal to that which is provided by 16-mm. home motion pictures and substantially exceeds that of the 8-mm. film widely used for amateur cinematography.

The physiological basis of this compromise lies in the fact that the normal eye, under conditions typical of television viewing, can resolve pictorial details if the angle they subtend at the eye is not less than two minutes of arc. This implies that the structure of 200,000 elements in a picture one foot high can just be resolved at a distance of about ten feet. The structure of the picture may be objectionably evident at short range, e.g., while tuning the receiver, but it is inappropriate to require the system to assume the heavy costs of transmitting detail which would be used by a small part of the audience for a small part of the viewing time.

The third item to be selected in image analysis is the shape of the picture. This has been standardized universally as a rectangle whose width is one-third longer than its height. This 4 by 3 ratio (aspect ratio) was originally chosen to match the dimensions of standard 35-mm. motion-picture film (prior to the advent of the wide-screen cinema) in the interest of televising film without waste of frame area. The width of the screen rectangle is greater than its height, as in the proscenium of a theatre, to accommodate the horizontal motion which predominates in virtually all televised events.

The fourth determination in image analysis is the path over which the image structure is explored at the camera and reconstituted on the receiver screen. In the original Nipkow disk, this path was a series of arcs of circles (fig. 1). In modern television, the pattern is a series of parallel straight lines, each progressing from left to right, the lines following in sequence from top to bottom of the picture frame. The exploration of the image structure proceeds at a constant speed along each line, since this provides uniform loading of the transmission channel under the demands of a given structural detail, no matter where in the frame the detail lies. The line-by-line, left-to-right, top-to-bottom dissection and reconstitution of television images is known as scanning, from its similarity to the progression of the line of vision in reading a page of printed matter. The agent which disassembles or reassembles the light values along each line is called the scanning spot, and the path it follows is the scanning pattern or raster.

The geometry of the modern scanning pattern is shown in fig. 2. It consists of two sets of lines. One set, marked A, is scanned first and the lines are so laid down that an equal empty space is maintained between lines. The second set, marked B, is laid down after the first, and is so positioned that its lines fall precisely in the empty spaces of set A. The area of the image is thus scanned twice, but each point in the area is passed over once. This is known as interlaced scanning, and is used in all the television broadcast services of the world. Each set of alternate lines is known as a scanning field; the two sets together, comprising the

whole scanning pattern, are known as a scanning frame. The repetition rate of field scanning is standardized in accordance with the frequency of electric power, as noted above, at either 50

Television Systems of the World

Region or country	Number of lines per frame	Number of pictures per second	Maximum detail (picture elements per frame)	Available picture band width (mc.)	Channel band width (mc.)
England	405	25	130,000	3	5
North America, South America, Japan	525	30	150,000	4	6
Europe, Australia, Africa, Eurasia	625	25	210,000	5*	7*
France and French dependencies	819	25	440,000	10.4	14

\*Six and eight megacycles respectively in U.S.S.R.

fields per second or 60 fields per second. The corresponding rates of frame scanning are 25 and 30 frames per second. The localities in which various scanning standards are used are listed in the table.

The total number of lines in the scanning pattern has been set to provide a maximum pictorial detail of the order of 200,000 picture elements. Since the frame area is 4 units wide by 3 units high, this figure implies a pattern of about 520 picture elements in its width (along each line) and 390 elements in its height (across the lines). This latter figure would imply a scanning pattern of about 400 lines, were it not for the fact that many of the picture details, falling in random positions on the scanning pattern, lie partly on two lines and hence require two lines for accurate reproduction. Scanning patterns are designed, therefore, to possess about 40% more lines than the number of picture elements to be reproduced in the vertical direction. Actual values in use in television broadcasting in various regions are 405 lines, 525 lines, 625 lines and 819 lines per frame, as listed in the table. These values have been chosen to suit the frequency band of the channel actually assigned in the respective geographical regions.

FIG. 3.—SCANNING PATTERN AND WAVE FORMS FOR HORIZONTAL AND VERTICAL DEFLECTION IN SEQUENTIAL PARALLEL-LINE SCANNING

The scanning spot is made to follow the paths shown in fig. 2 by imparting two repetitive motions to the spot simultaneously (fig. 3). One is a horizontally directed back-and-forth motion. The spot is moved at constant speed from left to right and then returned as rapidly as possible, while extinguished and inactive, from right to left.

Simultaneously, a vertical motion is imparted to the spot, moving it comparatively slowly from top to bottom of the frame. This motion spreads out the more rapid left-to-right scans, forming the first field scan of alternate lines and empty spaces. When the bottom of the frame is reached, the spot moves vertically upward as rapidly as possible, while extinguished and inactive. The next top-to-bottom motion then spreads out the horizontal line scans so that they fall in the empty spaces of the previously

scanned field. Precise interlacing of the successive field scans is facilitated if the total number of lines in the frame is an odd number. All the numbers of lines used in ordinary transmissions (see table) were so chosen.

The return of the scanning spot from right to left and from bottom to top of the frame, during which it is inactive, consumes time which cannot be devoted to transmitting picture information.

This time is used to transmit synchronizing control signals which keep the scanning process at the receiver in step with that at the transmitter. The time lost during retracing of the spot proportionately reduces the actual number of picture elements which can be reproduced. In the 525-line scanning pattern used in the U.S., about 15% of each line is lost in the return motion and about 35 out of the 525 lines are blanked out while the spot returns from bottom to top of two successive fields. The scanning area actually in use for reproduction of the picture contains a maximum of about 435 picture elements along each line and has 490 active lines, capable of reproducing 350 picture elements in the vertical direction. The frame can accommodate at maximum, therefore, about  $350 \times 435$  or 152,000 picture elements. The detail-transmission capacity of the scanning patterns of other systems is listed in the table.

The time taken by the scanning spot to move over the active portion of each scanning line is of the order of .000005 sec. (microseconds;  $\mu$  sec.). In the U.S. system, 525 lines are transmitted in  $\frac{1}{30}$  sec., which is equivalent to about  $64 \mu$  sec. per line. Up to 15% of this time is consumed in the horizontal retrace motion of the spot, leaving  $54 \mu$  sec. for active reproduction of as many as 435 picture elements in each line. This represents a maximum rate of  $435 \div 54 \times 10^{-6} \approx 8,000,000$  picture elements per second. Two picture elements can be approximately represented by one cycle of the transmission signal wave. The signal must therefore be capable of carrying components as high as four megacycles. The U.S. six-megacycle television channel provides a sufficient band of frequencies for this (plus an additional two megacycles for transmission of the sound program, to protect against interference and to meet the requirements of vestigial side-band transmission [see *The Television Channel*, below]).

The relation between number of lines, number of pictures per second and the frequency band needed to transmit the picture information is

$$F = \frac{1}{2} R = KLP$$

where  $F$  is the frequency band in cycles per second which must be transmitted,  $R$  is the rate of scanning picture elements per second,  $L$  is the number of lines per picture,  $P$  the number of pictures per second and  $K$  a factor (approximately 0.5) which takes into account the spot retrace losses, the aspect ratio and vertical resolution losses due to line straddling.

The relationship between the ideal and actual scanning patterns is shown in fig. 4. The part shown as darker is lost during the spot retraces. The remaining area of the pattern is actively employed in analyzing and synthesizing the picture information and is adjusted to have the 4 by 3 dimensions of the standard aspect ratio. In practice, some of the active area may also be hidden behind the decorative mask which surrounds the picture tube of the receiver, as shown by the dashed line.

FIG. 6.—WAVE FORM OF SYNCHRONIZING SIGNAL: H, LINE-SCANNING PERIOD; V, FIELD-SCANNING PERIOD

### A. THE TELEVISION PICTURE SIGNAL

The translation of the televised scene into its electrical counterpart results in a sequence of electrical impulses known as the television picture signal. This can be represented graphically as a signal wave form in which the electrical values (voltage or current) are plotted vertically against time, plotted horizontally. Corresponding to the electrical values and time, respectively, are the brightness of the image at each point on the scanning line and the position on the line of the point in question. These quantities are shown in fig. 5.

The television signal wave form is a continuous sequence of electrical values, corresponding with the brightnesses along each line, interspersed with blank periods representing the times during which the inactive scanning spot retraces from the end of one line to the beginning of the next. A blank interval also occurs when the scanning spot, having reached the bottom of the frame, retraces to the top.

Superimposed on the blank intervals are additional impulses, known as synchronization signals. The horizontal synchronization signal is a small impulse which occurs shortly after the completion of each scanning line. Its purpose is to cause the scanning spots at the transmitter and receiver to retrace to the next line at precisely the same instant. The vertical synchronization signal is a serrated series of impulses (fig. 6) which occurs shortly after the scanning spot has reached the bottom of the frame, causing the receiver and transmitter spots to retrace to the top in synchronism.

Since the signal wave form embodies all the picture information to be transmitted from camera to receiver screen, the television system must deliver the wave form to the picture tube of each receiver as accurately and as free from blemishes as possible. Unfortunately, virtually every item of equipment in the system (amplifiers, cables, transmitter, the transmitting antenna, the radio wave in space, the receiving antenna and the receiver circuits) conspires to distort the wave form or permits it to be contaminated by "noise" or interference.

Among the possible distortions (fig. 7) are: (1) failure to maintain the rapidity with which the wave form rises or falls as the scanning spot crosses a sharp boundary between light and dark areas of the image, producing a loss of detail or smear in the reproduced image; (2) the introduction of overshoots which cause excessively harsh outlines;

FIG. 7.—TRANSMISSION DEFECTS IN PICTURE SIGNAL WAVE FORMS

and (3) failure to maintain the average value of the wave form over extended periods, which causes the image as a whole to be too bright or too dark.

Throughout the system, amplifiers must be used to keep the television signal strong relative to the random electrical currents (noise) which are everywhere present. These random currents, caused by thermally induced motions of electrons in the circuits, cause interference having a speckled appearance, known as

"snow." Pictures received from distant stations are subject to this form of interference, since the radio wave is then so weak that it cannot override the random currents in the receiving antenna. Interference of a striated type may be caused by the signals of stations other than that to which the receiver is tuned. Care in the design of the receiver tuner and amplifier circuits is necessary to minimize such interference, and channels must be allocated to neighbouring communities at sufficient geographical separations and frequency intervals to protect the local service.

The television signal wave form can be conveyed within transmitting and receiving apparatus, and over short distances of wires and cable, in the form shown in fig. 5. For transmission over greater distances, however, as in network connections and over the air, the signal wave form must be imposed on a high-frequency carrier wave. The broadcast transmitter, for example, is actually a generator of very-high-frequency or ultrahigh-frequency alternating current; i.e., current which reverses its direction several tens or hundreds of millions of times per second. When such a current (known as the carrier current) is passed through the transmitting antenna, it produces a radio wave of the same frequency which travels through space and induces a weaker, but otherwise identical, current in the receiving antenna.

At the transmitter the picture signal wave form changes the strength, or amplitude, of the high-frequency carrier current by a process known as amplitude modulation. The alternations of the carrier current are thus constrained to take on a succession of amplitudes which match the shape of the signal wave form, as is revealed in the outline or envelope of the carrier current (fig. 8).

The functions of the television system which generate, transmit and utilize the television signal wave form are shown in fig. 9. The scene to be televised is focused by a lens on a camera tube, within the camera. A scanning spot within the camera tube is passed over the image in the scanning pattern of fig. 3, its motion being controlled by the synchronization generator. The latter equipment also renders the scanning spot inactive during its retrace motions and generates the synchronization signals mentioned above. The camera produces the signal wave form, but not the synchronizing signals. The latter are thereupon added to the signal and the complete signal wave form (fig. 5 and 6) is established. The signal is then amplified as required, by amplifiers capable of operating over the wide band of frequencies (from a few cycles per second to 4,000,000 or 5,000,000 cycles per second) necessary to preserve the precise shape of the wave form. In a transcontinental network, the signal may pass through more than 100 such amplifiers in tandem before it finally reaches the transmitter. There the wave form is amplified to a high power level.

FIG. 8.—TRANSMISSION OF PICTURE SIGNAL BY AMPLITUDE MODULATION OF A HIGH-FREQUENCY CARRIER WAVE: ENVELOPE (BROKEN LINE) HAS SHAPE OF PICTURE SIGNAL WAVE FORM

FIG. 9.—BLOCK DIAGRAM OF (A) TRANSMITTER, (B) RECEIVER

Concurrently, the carrier current is generated by other circuits of the transmitter. The signal wave form and carrier current are then combined in the modulator, which imposes the wave form on the carrier (fig. 8). The modulated carrier current may then be further amplified (typically to 10,000 or more watts) and finally passed through the transmitter antenna, which radiates the television radio wave. A similar current is induced in any receiving antenna within the service area but the current is enormously weakened by the outwardly diverging travel of the wave from the transmitter. Reception of excellent quality is possible when the power picked up by the receiving antenna is only 0.00000001 w.

The transmitter antenna must be as high and in as exposed a location as possible, since the radio waves tend to be intercepted by solid objects, including the earth's surface at the horizon. Reception beyond the horizon is possible, but the signal at such distances becomes rapidly weaker as it passes to the limit of the service area.

In the receiver, the current from the antenna is passed through a tuner, which separates it from other currents of different carrier frequencies which may be present from other stations. The desired current is then amplified in several successive amplifier stages, while still in the amplitude-modulated form. Passage through a detector follows. The picture signal wave form is thereby recovered and is passed through still another amplifier before being sent to the picture tube. The picture screen displays a scanning spot whose brightness is controlled by the picture signal. Simultaneously, the signal is applied to synchronizing circuits which abstract from it the synchronizing signals. These are used to control the motion of the scanning spot so that it traces out the scanning pattern in precise synchronism with the motion of the scanning spot in the camera.

Transmission and reception of the accompanying sound program are accomplished by the apparatus shown in fig. 10. The microphone produces a signal wave form which represents the sound pressure changes impinging on it. This wave form is amplified, transmitted over the network and finally fed to the sound transmitter. The latter, like the picture transmitter, is a generator of high-frequency carrier current, but of a frequency slightly different from that used to carry the picture information (for U.S. channel 2, the picture carrier is frequency 55.25 mc. while the sound carrier is 59.75 mc.).

For the sound transmission, however, a different modulation process is used, whereby the frequency, rather than the amplitude, of the carrier is changed by the sound wave form. This is frequency modulation (FM). The use of different forms of modulation for picture and sound makes for substantial simplification of receiver design. At the receiver, the sound carrier wave is tuned in simultaneously with the picture carrier wave, and the

two carrier currents are amplified in concert. The sound wave form is finally recovered in a frequency detector and is passed after further amplification, to the loud-speaker.

The amount of amplification conferred on the picture and sound currents by a typical television receiver is extremely large. When tuned to a station at a distance of 50 mi., the power picked up by the antenna is typically  $10^{-11}$  w., whereas the signals fed to picture tube and loud-speaker, after amplification, are of the order of 1 w. That is, the receiver produces a faithful amplification of the order of 100,000,000,000 times.

## B. TELEVISION CAMERA TUBES

The television camera tube is an electronic device which converts an optical image into a sequence of electrical impulses; i.e., it produces the television picture signal. Four types of television camera tube are in wide use: the image orthicon, the orthicon, the iconoscope and the Vidicon. These devices differ in detail but have in common the following elements: (1) a photosensitive surface, on which the scene to be televised is focused by a lens, which converts each light value into a corresponding value of electric charge and forms thereby an electrical image; (2) a means of storing the electrical image, that is, causing the charge to accumulate during the interval of several hundredths of a second between successive scanings of each line in the image; (3) an electron beam, formed in an electron gun and deflected over the electrical image, following the scanning pattern of fig. 2; and (4) a mechanism for producing an electrical current or voltage which is proportional at every instant to the electric charge accumulated at the point passed over by the electron beam at that instant. The latter is the picture signal represented in the wave form of fig. 5.

Means are also provided for extinguishing the scanning beam during its retrace motions, so that no television signal is then generated. Two other television pickup devices, which do not store the electrical image, are the flying spot scanner and the image dissector.

**1. Iconoscope.**—The iconoscope is obsolescent, since it is not as sensitive as the image orthicon and its images are subject to uneven shading and flare, but it is used in televising motion-picture film. Here it serves to introduce the concepts of electron image storage and scanning in simple form. The iconoscope is housed in a dipper-shaped vacuum-tight glass envelope, as shown in fig. 11. Within the wide end is a flat sheet of mica. A uniform metallic coating (the signal plate) is placed on the rear surface of this sheet, away from the image. The front surface of the mica is covered with a mosaic comprised of many hundreds of thousands of tiny globules of silver.

During the manufacture of the tube the mosaic is treated with cesium vapour and oxygen, so each globule has a surface of the oxides of silver and cesium. This combination of elements possesses a low electronic work function, that is, electrons are readily liberated, by the photoelectric effect, when light falls on the surface. Since the globules are insulated from each other and from the signal plate by the mica, the loss of electrons under illumination causes the globules to assume and hold a positive charge, the charge on each globule being proportional to the strength of the illumination falling on it and to the time it has been illuminated.

When an optical image is focused on the mosaic, the whole surface assumes a distribution of positive charge which matches

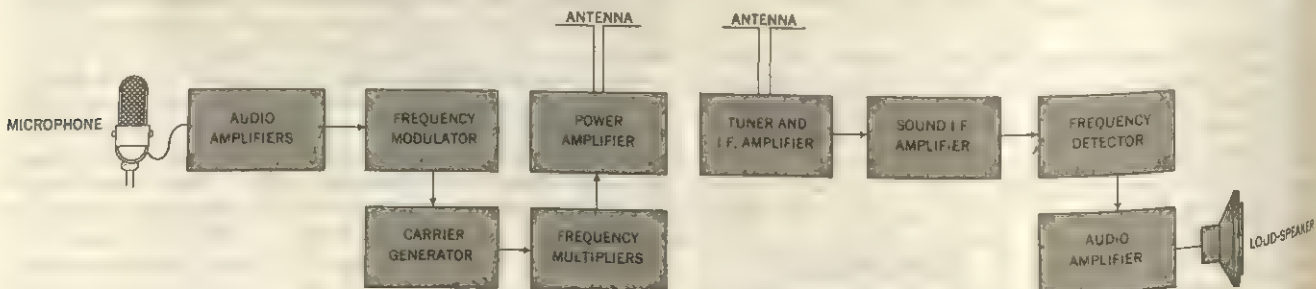

FIG. 10.—BLOCK DIAGRAM OF SOUND TRANSMISSION AND RECEPTION EQUIPMENT

FIG. 11.—ICONOSCOPE CAMERA TUBE

the distribution of light in the image, and the amount of charge at each point steadily increases until the scanning spot passes over the globule at that point.

The scanning spot of the iconoscope is formed by a narrow beam of electrons, shot out of an electron gun in the side arm of the tube. On its way to the mosaic this beam passes within two sets of electromagnet coils. Currents like those of fig. 3 are passed through these coils, causing the beam to be deflected horizontally at a rapid rate and vertically at a slower rate. The extent of the horizontal motion is adjusted from top to bottom of the mosaic, so that the pattern traced out by the electron beam on the mosaic is a rectangular pattern like that in fig. 2.

The electrons in the beam are accelerated to a relatively high velocity (the accelerating potential in the electron gun is of the order of 1,000 v.). When the beam hits a globule, therefore, it transfers a substantial amount of energy to the atoms of the globule and the globule surface gives off electrons (additional to those freed by the optical image) by virtue of the impact. This effect is known as secondary electron emission.

The number of secondary electrons thus liberated depends on the electrical potential which the globule in question has assumed under the prior influence of the light falling on it. As each globule is passed over by the beam, therefore, it undergoes a sudden change in electrical potential, the amount of the change being proportional to the light falling on it. The change in potential of the globule is transferred through the mica support to the signal plate behind it, the globule and plate forming in effect the plates of an electrical condenser. Thus, as the beam passes in succession over the globules lying along a given scanning line, the signal plate assumes a succession of voltages (the picture signal) which match the corresponding succession of light values along that line. The signal plate is connected to an amplifier, external to the iconoscope, which increases the strength of the picture signal.

The secondary electrons liberated by the impact of the scanning beam are in large part collected by a positively charged anode ring (fig. 11), but some of the electrons fall back on the mosaic in a random pattern, thus destroying to some degree the charge pattern produced by the optical image. This produces uneven shading and flare in the reproduced image, as previously mentioned.

The phenomenon of charge storage, by which the magnitude of the electrical image is continually increased between successive scanings of each line, is of the utmost significance in television technology. It will be remembered that the Nipkow disk (and other nonstorage television pickup devices) employs only the light which is present at a given point in the image at the instant the scanning spot passes over that point. Since in modern television the area of the scanning spot is only about  $\frac{1}{200,000}$  of the area of the scanning pattern, only this small fraction of the light of the image can be used. But when the image charge is stored in increasing amount for the full interval between successive scanings of a given point, the accumulated charge is then

theoretically about 200,000 times that which can be accumulated during the time the beam moves through its own width. In practice, the storage action makes the iconoscope about 100,000 times more sensitive than an equivalent camera tube operating without storage. This means that the light needed by the iconoscope is only  $\frac{1}{100,000}$  that needed by a nonstorage tube.

**2. Orthicon.**—The orthicon camera tube was the first successor to the iconoscope. A refined version (the CPS Emitron described below) is used in England for studio work. This tube (fig. 12) is housed in a cylindrical glass structure, on one end of which the optical image is focused on a mosaic. This mosaic is similar to that of the iconoscope, but is made up of a precise array of squares of photosensitive material, forming by evaporation on a transparent support. A transparent metal coating on the reverse side serves as the signal plate.

The optical image is focused on the signal plate, passing through it and the support to the mosaic, where it creates and stores a positive electrical charge image, in the manner of the iconoscope. The electron beam is formed in an electron gun at the other end of the tube and is directed toward the mosaic and deflected by electromagnet coils surrounding the tube so that it passes over the mosaic in the standard interlaced scanning pattern. The electrons are accelerated by a low voltage, so that they do not liberate any substantial number of secondary electrons. Instead, the negative electrons in the beam land on the mosaic squares, neutralizing the stored positive charge and ultimately building up a negative charge. The electrons in the beam are then repelled and return to the opposite end of the tube where they are removed by a positive collecting electrode which surrounds the electron gun. The change in electrical potential, undergone by each mosaic element as its charge is neutralized, is transferred by capacitive action, as in the iconoscope, to the signal plate. The latter thereby undergoes a succession of voltage changes which constitute the picture signal and which are passed to amplifier stages external to the tube.

The orthicon is unstable if subjected to high light levels. The CPS Emitron minimizes this difficulty by care in the design of the mosaic structure, but the tube operates best under closely controlled illumination and hence is used primarily in studios rather than in outdoor situations.

**3. Image Orthicon.**—The image orthicon is, by common consent, the most highly developed of the television camera tubes and is perhaps the most remarkable electronic device in existence. In its most refined form, its sensitivity to light is phenomenally great. It can respond to light levels far below those capable of exposing motion-picture film or affecting the eye itself (the "film speed" rating of such tubes is of the order of ASA 10,000). Less sensitive image orthicon tubes are used in broadcasting practice; they serve to produce satisfactory image quality under any light levels likely to be encountered in studio and outdoor scenes.

The image orthicon is similar to the orthicon but includes an additional electrical-imaging process and contains a high-gain amplifier based on the phenomenon of electron multiplication. It is used for virtually all live-scene telecasting in the United States, indoors and out.

The image orthicon (fig. 13) is housed in a cylindrical glass envelope having an enlarged section on one end, which is closed by an optically flat glass plate on the inside of which is deposited a continuous photosensitive coating (photocathode). The optical

BY COURTESY OF RADIO CORPORATION OF AMERICA

FIG. 12.—ORTHICON CAMERA TUBE

FIG. 13.—IMAGE ORTHICON CAMERA TUBE

image is focused through the glass support onto the coating, where it liberates electrons by photoelectric emission, the emission at each point matching the amount of light in the image at that point.

The liberated electrons stream away from the photosensitive surface, through the enlarged cylindrical portion of the tube, until they encounter the target electrode. This is a piece of very thin glass of uniform thickness. The streams of electrons induce secondary emission of electrons from the surface of the glass, and the latter are collected by a fine mesh screen (500 or more meshes to the inch). This lies parallel and close to the glass target; the streams of image electrons pass through it on their way to the target.

Since the glass target is very thin, its longitudinal electrical resistance, through its thickness, is small (resistance varies directly with the length of the conducting path). The changes in electrical potential induced by secondary emission are transferred through this low resistance to the opposite face of the target, where they are scanned by the electron beam. Conversely, the lateral resistance, across the face of the thin glass target, is very great (since electrical resistance varies inversely with the cross section of the conduction path). Consequently any tendency of the charge pattern to dissipate itself laterally is arrested, and the fine structure of the electrical image is preserved throughout the scanning interval. Moreover, as the streams of electrons from the photocathode continue to fall on the target glass, the intensity of the electrical image continually increases; that is, storage of charge occurs.

Both the photocathode and the target are continuous surfaces and in themselves contribute no structural limit to the detail of the image. The fine mesh screen which collects the secondary electrons from the target imposes the limit on detail, and consequently the holes in the screen must be substantially smaller than the scanning spot. Actually, the screen possesses nearly 1,000,000 holes in an area of 1.5 sq.in., compared with the roughly 200,000 picture elements into which the image is dissected.

The stored charge image on the reverse side of the target is scanned by an electron beam, which, like that of the orthicon, is accelerated at lower voltage and is actually decelerated before hitting the target, so that the scanning electrons have a velocity corresponding to voltage from zero to a few volts. Consequently, the secondary emission caused by scanning produces no deleterious effects.

The electron beam is deflected in the standard interlaced scanning pattern over the electrical image by magnetic fields produced by coils external to the tube. When the beam electrons hit the target, they neutralize the stored positive charge, as in the orthicon, and when equilibrium is reached, further electrons may not land on that spot. Thereafter, the electrons in the beam are turned around at the target and return to the vicinity of the electron gun at the other end of the tube. At this juncture the action differs from that of the orthicon. Instead of taking the picture signal from a signal plate at the target, the return beam of electrons is used. The number of electrons returning from each point in the scanning pattern is conditioned by the prior positive charge neutralization occurring at that point. Consequently the return beam constitutes a picture signal current.

When the return beam reaches the opposite end of the tube it is passed through an amplifier structure which contributes greatly to the sensitivity of the tube. This structure comprises several metal pin-wheel structures. The surfaces of the pin-wheel vanes

are treated to have low work function, and hence emit secondary electrons copiously when the return-beam electrons hit them. The pin-wheel shape causes the secondary electrons liberated at the first vane to be deflected to the next vane in the same structure, where still further emission of secondary electrons occurs. The magnified stream then passes to the next pin-wheel structure to the rear, where the process repeats and the electron stream is cumulatively multiplied.

Passage through this electron multiplier structure increases the strength of the television picture signal by several thousand times (in addition to the effect provided by storage at the target) with little addition of random noise current. The image orthicon thereby achieves a sensitivity greater than that of any other continuously registering optical device. The amplified current at the final stage of the electron multiplier is passed out of the tube to a conventional vacuum-tube amplifier.

**4. Vidicon.**—The Vidicon camera tube, first used in the early 1950s, was the first camera device to employ the phenomenon of photoconductivity. In its early form it was sluggish (objects in motion were reproduced with noticeable smear) and hence it was limited to industrial applications. Later versions were free of this defect and the Vidicon came to enjoy some use in broadcasting, in monochrome and colour service. The tube elements (fig. 14) are contained in a cylindrical glass envelope, substantially smaller than the image orthicon and hence more adaptable to portable cameras. At one end, a transparent metallic coating serves as a signal plate. Deposited directly on the signal plate is a photoconductive material (a complex compound of selenium) whose electrical resistance is high in the dark but progressively lowers as the amount of light increases.

The optical image is focused on the end of the tube and passes through the signal plate to the photoconductive layer, where the light induces a pattern of varying conductivity which matches the distribution of brightness in the optical image. The conduction paths through the layer allow positive charge from the signal plate (which is maintained at a positive voltage) to pass through the layer, and this current continues to flow during the interval between scans. Charge storage thus occurs, and an electrical charge image is built up on the rear surface of the photoconductor.

At the other end of the tube an electron beam is formed and passed through magnetic fields which deflect it, in the standard interlaced scanning pattern, over the rear surface of the photoconductive layer. The beam electrons neutralize the positive charge on each point in the electrical image and the resulting change in potential is transferred by capacitive action to the signal plate, from which the television signal is derived. There is no structural limit within the photoconductive layer itself; that is, the electron beam scanning spot imposes the only limit on the image detail.

It is possible, therefore, to derive an image of broadcast quality (200,000 picture elements) from a photosensitive area no larger than 0.2 sq.in. This permits the use of small and comparatively inexpensive lenses, with correspondingly large depth of focus for a given lens opening. The internal structure of the tube is very simple and this, with its small size, makes it adaptable to a wide range of camera arrangements in broadcasting, industrial and military applications.

BY COURTESY OF RADIO CORPORATION OF AMERICA

FIG. 14.—VIDICON CAMERA TUBE

FIG. 15.—IMAGE DISSECTOR CAMERA TUBE

**5. Image Dissector.**—The image dissector, originally developed by P. T. Farnsworth, was used in early experimental broadcasting, but has been replaced by the storage-type camera tubes described above. The tube, in cylindrical form (fig. 15), has a photocathode surface at one end on which the optical image is focused. Electrons are thereby liberated photoelectrically and stream from the photocathode toward the opposite end of the tube, the number of electrons arising from each point being proportional to the light falling on that point. An electron image is thereby produced, and the whole image is moved bodily by magnetic scanning fields passed through the tube from external coils.

At the other end of the tube is a closed metal finger with an aperture at its end. As the electron image is deflected past this aperture, electrons from the image enter the aperture. As the image passes, the electrons entering are representative of the succession of lights and shadows along each line in the scanning pattern. The electrons entering the aperture are, in effect, the television signal current. Within the finger is a succession of electron-multiplying surfaces which increase the current by successive secondary emission. The magnified current derived at the last surface is taken from the tube and subsequently amplified by vacuum tubes.

Since the current selected from the electron image by the aperture is limited to that liberated from the photocathode at the instant the aperture passes each point, no storage occurs, so the dissector requires many thousands of times as much light as the storage tubes described above to produce an image of acceptable quality. The electronic action of the tube is extremely straightforward, however, and it can produce an image of very high quality, free from incidental blemishes, if sufficient light is available. It is used only in industrial and military systems.

**6. Flying Spot Scanner.**—Another form of television pickup device, used in televising film transparencies, is the flying spot scanner (fig. 16). The light source is a cathode-ray tube in which a beam of electrons, deflected in the standard scanning pattern, impinges on a fluorescent phosphor surface. The beam produces thereby a spot of light which moves in the scanning pattern. The light from this spot is focused optically on the surface of the photographic film transparency to be televised. As the image of the spot moves, it traces out a scanning line across the film, and the amount of light emerging from the other side of the film at each point is determined by the transparency of the film at that point. The emerging light is collected and caused to enter a photoelectric cell which produces a current proportional to the light entering it.

This current thus takes on a succession of values proportional to the successive values of transparency along each line in the

FIG. 16.—FLYING SPOT CAMERA SYSTEM

scanning pattern, that is, it is the picture signal current. No storage action occurs, so the light from the cathode-ray tube must be very intense and the optical design very efficient to secure noise-free reproduction. The flying spot system may be used with motion-picture film if an optical immobilizer is used. (See *Television Recording*, below.)

### C. VIDEO AMPLIFICATION

The picture signal wave form produced by the television camera is initially very weak, of the order of a few hundredths of a volt, and is therefore ready prey to the random currents (noise) present in the succeeding transmission circuits. Immediately upon leaving the camera, therefore, the signal must be strengthened, and this process must be repeated at intervals throughout the transmission to the picture tube at the receiver. The strengthening process, known as video amplification, occurs in electron tubes with associated circuit elements which permit the extremely wide band of frequencies comprising the signal to be magnified without relative discrimination. The picture signal is applied to the grid (control electrode) of the electron tube, which governs the passage of electrons from the negative, electron-emitting element (cathode) to the positive, electron-collecting element (anode). Since the electrons pass from cathode to anode of an electron tube in a few thousandths of a millionth of a second, the grid is able to exercise control over the electron current several hundred million times per second, that is, at rates considerably above the 4,000,000 cycles per second (c.p.s.) upper frequency limit of the picture signal. The video amplifier must, however, provide uniform amplification throughout the band of frequencies from a lower limit near zero cycles per second to this upper limit. The amount of amplification tends to fall near the upper frequency limit, since it takes a finite time for the electron current of the tube to charge the electrical capacitance associated with the tube electrodes and the circuit elements. This tendency may be counteracted by inserting in the anode circuit of the amplifier a small inductance coil which resonates with the capacitance at a frequency above the upper limit of the picture signal spectrum.

At the other end of the spectrum, near zero frequency, the amplification also tends to fall off as a result of incomplete coupling between successive amplifier stages. This effect may be counteracted by care in proportioning the resistive and capacitive elements in the coupling connections, which makes possible uniform amplification down to about 30 c.p.s. However, it is impractical to reach zero frequency (direct current), since a succession of direct-current coupled amplifiers displays unmanageable instability. This difficulty is circumvented by arranging for the envelope of the broadcast carrier current to have a fixed amplitude at a level corresponding to black (absence of light in the televised scene). In this way the average brightness of the image may be preserved and recovered.

Electron tube video amplifiers can be designed to have a remarkably comprehensive range, amplifying a picture signal comprising any combination of frequency components lying between 30 and 4,000,000 c.p.s. This implies not merely that the amplitudes of all such components are uniformly increased, but that their relative times of occurrence are strictly preserved. Only if these requirements are met can the fine structure, as well as the gross outline, of the picture signal wave form be preserved from the camera to the receiver picture tube.

### D. THE TELEVISION CHANNEL

When the band of frequencies in the picture signal is imposed on the high-frequency broadcast carrier current in the modulator of the transmitter, as previously described (fig. 8), two bands of frequencies are produced above and below the carrier frequency. Thus, if the picture signal occupies a band of frequencies extending to four megacycles, two side bands are produced which extend four megacycles downward and four megacycles upward from the carrier frequency. The side bands are identical in frequency content, that is, both carry the complete picture signal information. One of the side bands is superfluous and, if transmitted, would wastefully consume space in the broadcast spectrum. Therefore,

the major portion of one of the side bands is removed, and the other is transmitted in full. Complete removal of the superfluous side band is possible, but this would complicate receiver design. Hence, a vestige of the unwanted side band is retained to serve the over-all economy of the system. This technique is known as vestigial side-band transmission. It is now universally employed in all the television broadcast systems of the world.

The television channel contains the picture carrier frequency, one complete picture side band and a vestigial portion of the other picture side band. In addition, the carrier for the sound transmission and its side bands is included within the channel. Since the band of frequencies needed to convey the sound is very much narrower than that needed for the picture, it is feasible to include both sound-carrier side bands. To avoid mutual interference between sound and picture, the picture and sound side bands must not overlap. Moreover, some space must be allowed at the edge of the channel to avoid interference with the transmissions of stations occupying the adjacent channels.

These requirements are met in the television channel shown in fig. 17. Each contains the following bands: 4.5 mc. for the fully transmitted picture side band, 1.25 mc. for the vestige of the other picture side band, 0.15 mc. for the sound carrier and its two side bands and the remaining 0.1 mc. to guard against overlap between picture and sound and between channels. In compatible colour transmissions an additional colour-information signal, known as the chrominance subcarrier, is included within the fully transmitted picture side band (fig. 23). A special technique (frequency interlacing, described under *Compatible Colour Television*, below) avoids interference between the two signals which then occupy a portion of the channel in common.

The television channels of the U.S. are assigned in the following segments of the spectrum: channels 2, 3 and 4, 54-72 mc.; 5 and 6, 76-88 mc.; 7 through 13, 174-216 mc.; and the UHF channels, 14 through 83, 470-890 mc. These channels are allocated to communities according to a master plan established and administered by the Federal Communications commission. No more than seven channels are provided in any one area (this number is allocated only to New York and Los Angeles). Many smaller cities must be content with one or two channels.

#### E. THE TELEVISION TRANSMITTER

The task of the television transmitter is to produce the picture and sound carriers, and their side bands, in conformity with the arrangement of the channel assigned to it. The electronic equipment which performs these functions is shown in fig. 18. The central element is the synchronizing generator, which controls the timing of the scanning of the camera and which produces the synchronizing impulses. It applies three control functions to the camera: timing for horizontal (line-by-line) deflection of the scanning beam; timing for vertical deflection (field-by-field); and the blanking impulses which extinguish the scanning spot during its retrace motions. The camera, under the control of the synchronizing generator, produces the picture signal without the synchronizing impulses. The picture signal is passed first through a preamplifier within the camera housing and then through additional amplifiers in the control room of the studio. In one of these amplifiers, the synchronizing impulses from the synchronizing generator are added to the picture signal. At this point, it is

FIG. 17.—ALLOCATION OF TELEVISION CHANNEL FOR MONOCHROME BROADCASTING

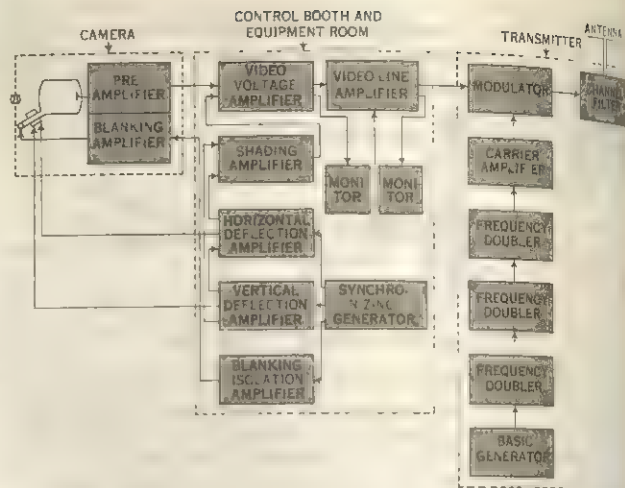

FIG. 18.—DETAILED BLOCK DIAGRAM OF MONOCHROME TRANSMITTER

customary to inspect the quality of the reproduced image by feeding the signal to a monitor which displays the image on a picture tube. The monitor screen is viewed by the program director and operating personnel. Any shortcomings are corrected by instructions telephoned to the camera operator or by adjustment of video controls in the control room. Simultaneously the audio controls are used to adjust the sound signal.

The adjusted picture and sound signals are fed to the network which interconnects stations or, in local broadcasts, to cables leading directly to the transmitter. The latter is usually located at some distance from the studio to permit placing the transmitting antenna in as favourable a location as possible with respect to the intended service area.

The transmitter performs two functions: generation of the carrier currents for picture and sound, and imposition of the sound and picture signals on the respective carrier currents. Precautions are taken to assure that the frequencies of the carrier waves have precisely the values assigned to the channel in use. Small wafers of quartz, which vibrate under electrical forces by virtue of the piezoelectric effect, are used as the basic sources of the carrier currents. The frequency at which quartz can vibrate is lower than that of the intended radio waves, so the current is passed through a succession of frequency-doubling circuits until it reaches the required value. The resulting carrier currents have frequencies accurate to roughly one part in 200,000.

The carrier current and the picture signal are combined in the modulator, which modulates the envelope of the carrier as previously described (fig. 8). The modulated carrier contains two identical side bands. The major portion of one of these (that occupying frequencies below the carrier) is removed by a wave filter, and the remaining part, plus the picture carrier current and the fully transmitted side-band currents, are passed to the transmitting antenna. A similar arrangement (carrier-current generator, frequency multipliers and frequency modulator) produces the sound carrier current and its side bands. These are also fed to the transmitting antenna, which is designed to direct the radiated waves toward the surface of the earth and to minimize radiation toward the sky.

#### F. THE TELEVISION RECEIVER

At the receiver (fig. 19), the sound and picture carrier waves pass through the rods of the receiving antenna, inducing currents which are identical in form to those flowing in the transmitter aerial, but much weaker. The carrier currents and their side bands are conducted from the antenna to the receiver by a lead-in transmission line, typically a  $\frac{1}{2}$ -in. ribbon of polyethylene plastic in which are embedded two parallel copper wires. This form of transmission line is capable of passing the carrier currents to the receiver, without relative discrimination between frequencies, on all the channels to which the receiver may be tuned.

At the antenna terminals of the receiver, the picture and sound signals are at their weakest, so particular care must be taken to

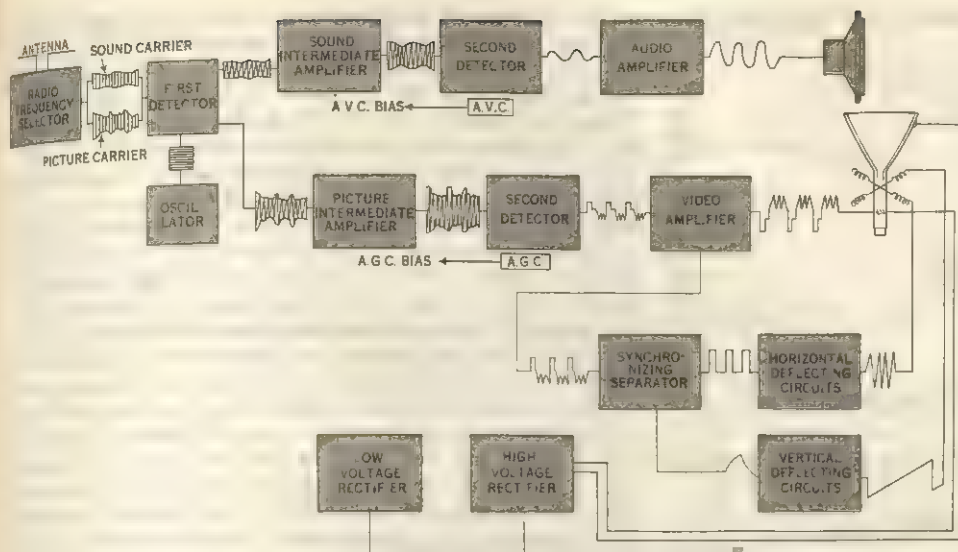

FIG. 19.—BLOCK DIAGRAM OF MONOCHROME RECEIVER, SHOWING WAVE FORM BETWEEN COMPONENTS

control noise at this point. The first circuit in the receiver is a radio-frequency amplifier, particularly designed for low-noise amplification. The channel-switching mechanism (tuner) of the receiver connects one of several individual circuits to this amplifier, each tuned to its respective channel. This amplifier magnifies the voltages of the incoming picture and sound carriers and side bands in the desired channel by about ten times and it discriminates by a like amount against the transmissions of stations on other channels.

From the radio-frequency amplifier, the signals are passed to the superheterodyne mixer, also a part of the tuning mechanism. This is a circuit that transposes the frequencies of the sound and picture carriers to values better suited to the subsequent amplification processes. The transposed frequencies (intermediate frequencies) remain the same, no matter what channel the receiver is tuned to. In typical receivers they are located in the band from 41 to 47 mc.

Since the tuning of the subsequent amplifiers (intermediate-frequency amplifiers) need not be changed as the channel is switched, they can be adjusted for maximum performance in the 41-47-mc. range. Three or four stages of such amplification are used in tandem, increasing the voltage of the picture and sound carriers by a maximum of 25 to 35 times per stage, representing an over-all maximum amplification of the order of 10,000 times. The amplification of these intermediate-frequency stages is automatically adjusted by a process known as automatic gain control in accordance with the strength of the signal, full amplification being accorded to a weak signal, less to a strong signal. After passage through the intermediate amplifiers, the sound and picture carriers and their side bands reach a relatively fixed level of about one volt, whereas the signal levels applied to the antenna terminals may vary, depending on the distance of the station and other factors, from a few millionths to a few tenths of a volt.

From the last intermediate amplifier stage, the carriers and side bands are passed to another circuit, known as the video detector. This removes one-half of each alternation of the signal currents, converting the alternating current into pulsating direct current. An averaging circuit or filter then forms, from the direct-current pulsations (1) a picture signal, which is a close replica of the picture signal produced by the camera and synchronizing generator in the transmitter, and (2) a frequency-modulated sound signal whose variations in frequency match the variations in sound pressure which impinged on the studio microphone. Thus far, the picture and sound signals are handled simultaneously in each amplifier and detector circuit. Both may also be passed through a video amplifier which increases their voltage by about ten times.

At this point the picture and sound signals separate. Another

video amplifier passes the picture signal to the picture tube, where it controls the brightness of the scanning spot. Simultaneously, the picture signal wave form is passed to a circuit (the synchronizing signal separator) which selects the blank periods in the wave form (fig. 5 and 6) and the superimposed synchronizing signals.

Finally, the sound signal is passed through a frequency detector (discriminator or ratio detector) which converts the frequency modulations into pulsations representative of the sound pressure variations. This current, an accurate replica of the current produced by the studio microphone, is passed through one or two additional audio-frequency amplifier stages to the loud-speaker, which reproduces

the sound waves in conformity to those in the studio.

Meanwhile, back at the synchronizing signal separator, the synchronizing signals are passed through filters which separate the horizontal synchronizing impulses (fig. 5) from the serrated vertical synchronizing impulses (fig. 6). The synchronizing impulses are then passed, respectively, to the horizontal and vertical deflection generators. These produce the currents that flow through the electromagnet deflection coils, causing the scanning spot of the picture tube to be deflected across the viewing screen in the standard scanning pattern.

The synchronizing signals control the timing of these currents, causing the scanning spot of the receiver to move synchronously with that of the camera. Pains are taken in the synchronizing action of the receiver to prevent the scanning motion from being disturbed by interference, since such disturbances would displace the picture elements from their correct positions in the pattern. It is one of the achievements of the modern television system that the scanning pattern is stably reproduced even when the picture signal is so infested with noise that the picture elements themselves are barely recognizable.

In addition to the amplifiers, detectors and deflection generators described above, the receiver contains two power-converting circuits. One of these (the low-voltage power supply) converts the alternating current from the power line into the direct current needed for the vacuum tube circuits; the other (high-voltage power supply) produces the high voltage, typically 15,000 to 18,000 v., needed to create the scanning spot in the picture tube.

The receiver controls commonly provided for adjustment by the viewer are: (1) the channel switch, which connects the required circuits to the radio-frequency amplifier and superheterodyne mixer to amplify and convert the sound and picture carriers of the desired channel; (2) a fine tuning control which precisely adjusts the superheterodyne mixer so that the response of the tuner is exactly centred on the channel in use; (3) a contrast control which adjusts the voltage level reached by the picture signal in the video amplifiers, producing a picture having more or less contrast (greater or less range between the blacks and whites of the image); (4) a brightness control which adjusts the average amount of current taken by the picture tube from the high-voltage power supply, thus varying the over-all brightness of the picture; (5) a horizontal-hold control, which adjusts the horizontal deflection generator so that it conforms exactly to the control of the horizontal synchronizing impulses; and (6) a vertical-hold control, which performs the same function for the vertical deflection generator. Additional adjustments provided for the serviceman include adjustments for the height and width of the picture (magnitudes of the deflection currents) and adjustments (linearity controls) to secure precisely uniform rates of horizontal and ver-

FIG. 20.—BASIC ELEMENTS OF MONOCHROME PICTURE TUBE

tical scanning so as to avoid distortion of the shapes of the objects in the picture.

### G. TELEVISION PICTURE TUBES

The television picture tube is illustrated in fig. 20. The tube is a highly evacuated, funnel-shaped structure. The viewing screen is located inside the tube face, a curved glass plate which closes the wide end of the funnel. The screen itself is composed of fluorescent materials, a mixture of two complex chemical compounds such as silver-activated zinc sulfide and silver-activated zinc cadmium sulfide. These materials, known as phosphors, glow with blue and yellow light, respectively, under the impact of high-speed electrons. The phosphors are mixed, in a fine dispersion, in such proportion that the combination of yellow and blue light produces white light of slightly bluish cast. A water suspension of these materials is settled on the inside of the face plate of the tube during manufacture, and this coating is overlaid with a film of aluminum sufficiently thin to permit the bombarding electrons to pass without hindrance. The aluminum provides a mirror surface which prevents the backward-emitted light from being lost in the interior of the tube and reflects it forward to the viewer.

At the opposite end of the tube is the electron gun (fig. 21), a cylindrical metal structure which generates and directs a stream of free electrons, the electron beam. At the rear of the electron gun is the cathode, a flat metal support covered with oxides of barium and strontium. These oxides have a low electronic work function; when heated by the heater coil behind the metal support they liberate electrons. In the absence of electric attraction, the free electrons form a cloud immediately in front of the oxide surface.

Directly in front of the cathode is the cylindrical sleeve of the gun, which is made electrically positive with respect to the cathode. The positively charged sleeve (first anode) draws the negative electrons away from the cloud and they move down the sleeve toward the viewing screen at the opposite end of the tube. They are intercepted, however, by a flat disk (the control electrode) having a small circular aperture at its centre. Some of the moving electrons pass through the aperture; others are held back.

The television picture signal is applied, from the video amplifier previously mentioned, between the control electrode and the cathode. During those portions of the picture signal wave form which make the potential of the control electrode less negative, more electrons are permitted to pass through the control aperture,

FIG. 21.—ELEMENTS OF PICTURE TUBE ELECTRON GUN

whereas during the more negative portions of the wave, fewer electrons pass. The brightness control applies a steady (but adjustable) voltage between control electrode and cathode. This voltage determines the average number of electrons passing through the aperture, whereas the picture signal causes the number of electrons passing the aperture to vary from the average.

From the aperture, the controlled stream of electrons passes down the anode sleeve into the glass neck of the tube. Inside the latter is a graphite coating, which extends throughout the funnel of the tube and connects to the aluminum back coating of the phosphor screen. The full value of positive high voltage (typically 15,000 v.) is applied to this coating and it therefore attracts the electrons from the sleeve along the neck into the funnel and toward the screen of the tube. As the electrons emerge from the sleeve and come under the influence of the graphite coating, each electron experiences a force which directs it toward the centre of the viewing screen. The electron beam is thus brought to focus on the screen and the light there produced is the scanning spot. Additional focusing forces may also be provided by an adjustable permanent magnet surrounding the neck of the tube, which introduces magnetic lines of force parallel to the direction of the electron beam. The scanning spot must be intrinsically very brilliant since (by virtue of the integrating property of the eye) the light in the spot is effectively spread out over the whole area of the screen during scanning.

Scanning is accomplished, as previously outlined, by two sets of electromagnet coils wound on a core of magnetic material. These coils must be precisely designed to preserve the focus of the scanning spot no matter where it falls on the screen, and the magnetic fields they produce must be so distributed that the deflections across each line and from line to line occur at uniform velocities.

Deflection of the beam occurs by virtue of the fact that an electron in motion through a magnetic field experiences a force at right angles both to its direction of motion and to the direction of the magnetic lines of force. The deflecting magnetic field is passed through the neck of the tube at right angles to the electron-beam direction and the beam incurs a force tending to change its direction at right angles to its motion, the amount of the force being proportional to the amount of current flowing in the deflecting coils.

To cause uniform motion along each line, the current in the horizontal deflection coil, initially negative, becomes steadily smaller, reaching zero when the spot passes the centre of the line and then increasing in the positive direction until the end of the line is reached. The current is then reversed and very rapidly goes through the reverse sequence of values, bringing the scanning spot to the beginning of the next line. The rapid rate of change of current during the retrace motions causes pulses of a high voltage to appear across the circuit feeding current to the coil and the succession of these pulses, smoothed into direct current by a rectifier tube, serves as the high-voltage power supply.

A similar action in the vertical deflection coils produces the vertical scanning motion. The two sets of deflection coils are combined in a structure known as the deflection yoke which surrounds the neck of the picture tube, directly at the junction of the neck with the funnel section.

Picture tubes vary in screen size and measurements are made diagonally across the tube face. The 17-in. size is frequently used in portable receivers, the 21-in. size in table and console model receivers. The design trend has called for greater angles of deflection, with correspondingly wider funnel sections and shallower over-all depth from electron gun to viewing screen. The increase in deflection angle from 55° in the first (1946) models to 110° in models produced in the 1960s required corresponding refinement of the deflection system because of the higher deflection currents required and the greater tendency of the scanning spot to go out of focus at the edges of the screen.

### IV. COMPATIBLE COLOUR TELEVISION

The technique of compatible colour television comprises two transmissions. One of these, the luminance transmission, employs

methods essentially identical to those of the monochrome television system. The second, the chrominance transmission, has virtually no effect on monochrome receivers. When used with the luminance transmission in a colour receiver, however, it produces an image in full colour.

The luminance-chrominance method of representing colour values is one of several alternative ways in which coloured light may be analyzed and synthesized. This method is particularly appropriate in a television system since it produces a compatible signal which can serve both black-and-white and colour receivers by one and the same broadcast.

Historically, compatibility was of great importance because it allowed colour transmissions to be introduced without obsolescence of the many millions of monochrome receivers in use. In a larger sense, the luminance-chrominance method of colour transmission is advantageous because it utilizes the limited channels of the radio spectrum more efficiently than other colour transmission methods.

To create the luminance-chrominance values, it is necessary (in the present state of the art) first to analyze each colour in the scene into primary colours. Coloured light may thus be analyzed by passing the light through three coloured filters, typically red, green and blue. The amounts of light passing through each filter, plus a description of the colour transmission properties of the filters, serve uniquely to characterize the coloured light.

The fact that virtually the whole range of colours may be synthesized from only three primary colours is essentially a description of the process by which the eye and mind of the observer recognize and distinguish colours. This process, like visual persistence, is a very fortunate property of vision, since it permits a simple three-part specification to represent any of the 10,000 or more colours and brightnesses which may be distinguished by human vision. If vision were dependent on the energy  $v$  wave length relationship (the physical method of specification), it is doubtful if colour reproduction could be incorporated in any mass-communication system.

By transforming the primary-colour values, it is possible to specify any coloured light by three other numbers: (1) its luminance (brightness or "brilliance"); (2) its hue (the redness, orangeness, blueness or greenness, etc., of the light); and (3) its saturation (its vivid  $v$  pastel quality). If the intended luminance value of each point in the scanning pattern is transmitted by the methods of the monochrome television system, it is only necessary

FIG. 23.—ALLOCATION OF TELEVISION CHANNEL FOR COMPATIBLE COLOUR TRANSMISSION

to transmit, via an additional two-valued signal, supplementary information giving the hue and saturation of the intended colour at the respective points in the scanning pattern.

Chrominance, defined as that part of the colour specification remaining when the luminance is removed, represents two independent quantities, hue and saturation. These may be represented graphically in polar co-ordinates (fig. 22) with saturation as the radius and hue as the angle. The centre of the diagram represents white light (the colour of zero saturation). Points on the outermost circle represent the most saturated colours, arranged counterclockwise in the order in which they appear in the spectrum from red to blue. Points on any radius of the diagram represent all colours of the same hue, the saturation becoming less (the colour less vivid or more pastel) as the point approaches the central "white point." A diagram of this type is the basis of the international standard system of colour specification.

In the compatible colour television system, the chrominance signal is an alternating current of precisely specified frequency ( $3.579545 \pm 0.000010$  mc.), the precision permitting its accurate recovery at the receiver even in the presence of severe noise or interference. Any change in the amplitude of its alternations at any instant corresponds to a change in the saturation of the colours being passed over by the scanning spot at that instant, whereas a shift in time of its alternations (a change in the phase angle of the alternations) similarly corresponds to a shift in the hue.

As the different saturations and hues along each scanning line are successively uncovered by scanning in the camera, the amplitude and phase, respectively, of the chrominance signal change accordingly. The chrominance signal is thereby simultaneously modulated in amplitude and in phase. This doubly modulated signal is imposed on the picture signal carrier current, along with the luminance signal.

The television channel, when occupied by such a compatible colour transmission, appears as shown in fig. 23 (compare this with the channel when occupied by a black-and-white transmission, fig. 17). The chrominance signal takes the form of a sub-carrier located precisely 3.579545 mc. from the picture carrier frequency. The picture carrier is thus simultaneously amplitude modulated by the luminance signal to represent changes in the intended luminance, and by the chrominance subcarrier which, in turn, is amplitude modulated to represent changes in the intended saturation and phase modulated to represent changes in the intended hue.

When compatible colour transmissions are received on a monochrome receiver, the receiver treats the chrominance subcarrier as though it were a part of the intended monochrome transmission. If steps were not taken to prevent it, the subcarrier would produce interference in the form of a fine dot pattern; that is, the subcarrier would change the brightness of the scanning spot 3,580,000 times per second, or about 190 times during the 0.000053 sec. consumed by the active scanning of each line. The dot pattern, fortunately, can be rendered almost invisible in monochrome reception by deriving the timing of the scanning motions directly from the source that establishes the chrominance subcarrier itself. The dot pattern of interference from the chrominance signal therefore can be made to have opposite effects on successive scanings of the pattern; that is, a point brightened by the dot inter-

FIG. 22.—HUE AND SATURATION (CHROMINANCE) VALUES ARRANGED IN POLAR CO-ORDINATES

ference on one line scan is darkened an equal amount on the next scan of that line, and the net effect of the interference, integrated in the eye over successive scans, is virtually zero. Thus, the monochrome receiver in effect ignores the chrominance component of the transmission. It deals with the luminance signal in the conventional manner, producing from it a monochrome image. This monochrome rendition, incidentally, is not a compromise; it is essentially identical to the image that would be produced by a monochrome television system viewing the same scene.

The channel for colour transmissions (fig. 23), when used by colour receivers, would appear to be affected by mutual interference between the luminance and chrominance components, since these occupy a portion of the channel in common. Such interference is avoided by the fact that the chrominance sub-carrier component is rigidly timed to the scanning motions. The luminance signal, as it occupies the channel, is actually concentrated in a multitude of small spectrum segments, by virtue of the periodicities associated with the scanning process. Between these segments are empty channel spaces of approximately equal size. The chrominance signal, arising from the same scanning process, is similarly concentrated. Hence it is possible to place the chrominance channel segments within the empty spaces between the luminance segments, provided that the two sets of segments have a precisely fixed frequency relationship. The necessary relationship is provided by the direct control by the subcarrier of the timing of the scanning motions. This intersegmentation is known as frequency interlacing. It is one of the fundamentals of the compatible colour system, and without it the superposition of colour information on a channel originally devised for monochrome transmissions would not be feasible.

When a colour receiver is tuned to the transmission represented in fig. 23, the picture signal is recovered in a video detector in the usual manner. An amplifier stage, tuned to the 3.58 mc. chrominance frequency, then selects the chrominance from the picture signal and passes it to a synchronous detector which recovers independently the amplitude-modulated and phase-modulated components. The synchronous detection process recovers the phase-modulated component by measuring the signal alternations against a reference timing signal transmitted during a part of the retrace motion between scanning lines. The detector is also simultaneously responsive to the amplitude-modulated components, in the manner of the video detector in monochrome reception.

#### A. COLOUR CAMERA AND PICTURE TUBE

The terminals of the colour television system, the camera and picture tube, analyze and synthesize, respectively, the colour quantities present at each point in the scanning pattern. The television camera in its current state of development does not produce the luminance, hue and saturation values directly. Rather it produces three picture signals, representative of the amounts of three primary colours present at each point in the image pattern. From these signals the luminance and chrominance components are then derived by manipulation in electronic circuits.

FIG. 24.—SCHEMATIC DIAGRAM SHOWING SELECTIVE SEPARATION OF LIGHT IN COLOUR CAMERA

FIG. 25.—COLOUR PICTURE TUBE EMPLOYING THE SHADOW-MASK PRINCIPLE

The typical colour television camera (fig. 24) contains three image orthicon tubes, with an optical system which casts an identical image on the sensitive surface of each tube. The optics comprise a lens and four mirrors which reflect the image rays from the lens onto the three camera tubes, as shown. Two of the mirrors are of a colour-selective type (dichroic mirror) which reflects light of one colour and transmits the remaining colours. The mirrors, plus colour filters which perfect their colour-selective action, direct a blue image to the first tube, a green image to the second tube and a red image to the third tube.

The deflection systems of the three camera tubes are arranged to produce essentially identical scanning patterns in each tube, so the picture signals developed by the respective tubes represent images of the same geometrical shape, differing only in colour. The respective primary-colour signals are passed through video preamplifiers associated with each camera tube and emerge from the camera as separate entities. If compatibility were not required, and if sufficient space were available in the radio spectrum, the three signals might be transmitted to the receiver over separate channels. Actually, as mentioned above, the primary-colour signals are recast into luminance and chrominance components; at the receiver the latter are converted back into primary-colour signals before application to the colour picture tube.

The colour picture tube (fig. 25) contains three electron guns which produce three separate electron beams. These are deflected simultaneously in the standard scanning pattern over the viewing screen. One of the beams is controlled by the red primary-colour signal and produces a red image. The second beam produces a blue image and the third a green image.

To permit three primary-colour images to be formed simultaneously, the screen is composed of three sets of individual phosphor dots, which glow respectively in the three different colours and which are uniformly interspersed over the screen (fig. 25). The "red" beam impinges only on the red-glowing phosphor dots, being prevented from hitting the other two colours, with similar restriction of the other two beams to the blue and green dots respectively.

The sorting out of the three beams so that they produce images of only the intended primary colour is performed by a mask which lies directly behind the phosphor screen. This mask contains about 200,000 precisely located holes, each accurately aligned with three different coloured phosphor dots on the screen in front of it. Electrons from the three guns pass together through each hole, but at slightly different angles. The angles are such that the electrons arising from the gun controlled by the red primary-colour signal fall only on the red dots, being prevented from hitting the blue and green dots by the shadowing action of the mask. Similarly, the "blue" and "green" electrons fall only on the blue and green dots, respectively.

In this manner three separate primary-colour images are formed simultaneously, as the scanning proceeds. The colour dots of which each image is formed are so small and so uniformly dispersed that the eye does not detect their separate presence. The primary colours in the three images thereby mix in the mind of the viewer and a full-colour rendition of the image results.

This type of colour tube is known as the shadow-mask tube. It has several shortcomings: (1) the electrons intercepted by the mask cannot produce light and the image brightness is thereby limited; (2) great precision is needed to achieve correct alignment of the electron beams, the mask holes and the phosphor dots at all points in the scanning pattern; and (3) precisely congruent scanning patterns, as among the three beams, must be produced. However, no other type of colour tube had been offered to the public by the mid-1960s. Other colour tubes, employing only one electron beam which sequentially excites stripes of primary-colour phosphors, and hence free of many of the alignment and congruence problems, were under development.

### B. COLOUR TRANSMITTER AND RECEIVER

Fig. 26 shows the essential elements of the colour transmitter, as they differ from the monochrome transmitter shown in fig. 18. Immediately following the colour camera is the colour coder which converts the primary-colour signals into the luminance and chrominance signals.

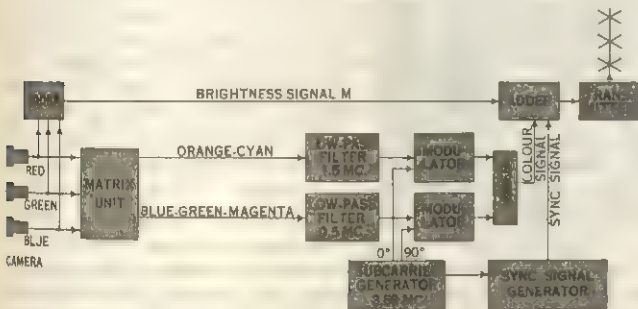

FIG. 26.—BLOCK DIAGRAM OF COLOUR TRANSMITTER

FIG. 27.—PICTURE SIGNAL WAVE FORM FOR COLOUR TRANSMISSION

At this stage, the colour picture signal can be handled in the same manner as the monochrome signal, except that throughout the network and in the transmitter special precautions must be taken to transmit the chrominance subcarrier at its correct amplitude, with its amplitude and phase modulations preserved against incidental distortions.

The colour receiver (fig. 28) contains a tuner and intermediate-frequency amplifiers similar to those used in monochrome receivers, but specially designed to preserve the chrominance subcarrier during its passage through these stages. The colour receiver also has power supplies, sound reception circuits and synchronization and deflection current generators similar to those used in monochrome reception.

The colour reproduction processes are divided into the luminance and chrominance functions. A video detector develops the luminance component and applies it through video amplifiers simultaneously to all three electron guns of the picture tube. This part of the signal thereby activates all three primary-colour images, simultaneously and identically, in the fixed proportion needed to produce white light. When tuned to monochrome broadcasts, the colour receiver produces a monochrome image by means of this mechanism, the chrominance component then being absent.

When the receiver is tuned to a colour broadcast, the chrominance subcarrier component appears in the output of the video detector and it is thereupon operated on in circuits which ultimately recover the primary-colour signals originally produced by the colour camera. The recovery starts in the synchronous detector. This is followed by circuits which perform the inverse operations of the addition and subtraction circuits at the transmitter. The end result of this manipulation is the production of three colour-difference signals which represent, respectively, the difference between the luminance signal, already applied to all three electron guns of the picture tube, and the primary-colour signals.

The three colour-difference signals are applied separately to the respective electron guns, where each reduces the strength of the corresponding electron beam to change the white light, which would otherwise be produced, to the intended colour for each point in the scanning line. The net control signal applied to each electron gun bears a direct correspondence to the primary colour signal derived from the respective camera tube at the studio. In

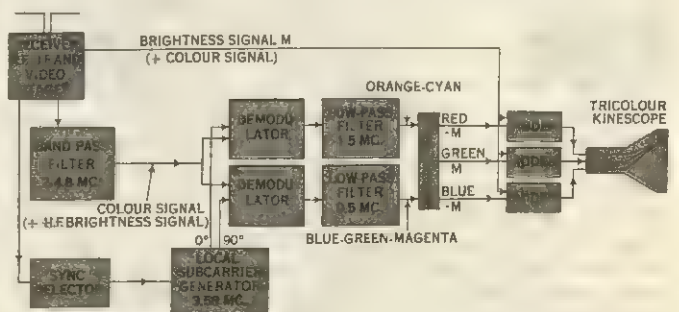

FIG. 28.—BLOCK DIAGRAM OF COLOUR RECEIVER

minance signals. The luminance signal is formed simply by applying the primary-colour signals to an electronic addition circuit which adds the values of the three signals at each point along the respective picture signal wave form. Since white light results from the addition, in appropriate proportions, of the primary colours, the resulting sum signal represents the black-and-white (luminance) version of the colour image. The luminance signal thus formed is subtracted individually, in three electronic subtraction circuits, from the original primary-colour signals, and the colour-difference signals are then further combined to produce two signals, which represent points on the orange-cyan and green-magenta axes of the chrominance diagram (fig. 22). These signals are then applied simultaneously to a modulator, where they are mixed with the chrominance subcarrier signal. The latter is thereby amplitude modulated in accordance with the saturation values and phase modulated in accordance with the hues. The luminance and chrominance components are then combined to form the over-all colour picture signal (fig. 27), which is then carried to the transmitter over the network or studio-transmitter link.

The chrominance subcarrier is generated in a precise electronic oscillator at the standard value of 3.579545 mc. Samples of this subcarrier are injected into the signal wave form during the blank period between line scans just after the horizontal synchronizing pulses. These samples are employed in the receiver to control the synchronous detector, mentioned above. Finally, the horizontal and vertical deflection currents, which produce the scanning in the three camera tubes, are formed in a scanning generator whose timing is controlled by the chrominance subcarrier. This common timing of deflection and chrominance transmission produces the dot-interference cancellation in monochrome reception, noted above.

this manner, the three primary-colour signals are transmitted as though three separate channels had been used.

The colour receiver controls to be adjusted by the viewer (in addition to the tuning, brightness, contrast and synchronizing controls present in monochrome receivers) are the hue control and the saturation control. The hue control adjusts the timing of the synchronous detector. It sets the reference phase against which the phase modulation of the chrominance subcarrier is measured, and hence shifts all the hues in the reproduced image. The hue control is usually adjusted by reference to the colour of the flesh of the performers, since unnatural flesh tone is readily recognized even if the viewer has no knowledge of the intended hues in other parts of the scene. The saturation control adjusts the magnitudes of the colour-difference signals applied to the electron guns of the picture tube. If these magnitudes are reduced to zero, by turning the saturation control to the "off" position, no colour difference action occurs and the reproduction occurs in monochrome. As the saturation control is advanced, the colour differences become more accentuated, and the colours become progressively more vivid. This control is adjusted to suit the personal preference of the viewer. Natural appearance of flesh tone is an appropriate index.

### V. TELEVISION RECORDING

Recording of television programs on photographic film or magnetic tape is an important technique, not only to preserve a permanent record of a live-scene program for subsequent rebroadcast, but also to perfect a performance, prior to its initial presentation, by the photographing and editing methods of the motion-picture industry. Recorded segments are often used in a "live" studio program when it is impractical to set up the desired scene in the studio. Transmission of films originally produced for motion-picture theatres is also a major activity in broadcasting.

Television film projectors fall into two classes, continuous and intermittent, according to the type of film motion. In the continuous projector, a scanning spot from a flying spot camera tube is passed through a rotating optical system, known as an immobilizer, which focuses the scanning spot on the motion-picture film. As the film moves continuously through the projector, the immobilizer causes the scanning pattern as a whole to follow the motion of the film frame, so that there is no relative motion between pattern and frame. The light passes through the film to a phototube where the light, modified by the transmissibility of the film at each point, produces the picture signal. As one film frame moves out of the range of the immobilizer, the next moves into range and there is a condition of overlap between successive scanning patterns.

The optics are so arranged that the amount of light in the spot focused on the film is constant at all times and in all positions. This constancy permits the film to be moved at any desired speed, while the pattern scans at the standard rate of 25 or 30 pictures per second. The film is actually moved at the standard rate for motion pictures, 24 frames per second, so the speed of objects and pitch of the accompanying sounds (picked up from the sound track by conventional methods) are reproduced at the intended values.

In the intermittent projector, which more nearly resembles the type used in theatre projection, each frame of film is momentarily held stationary in the projector while a brief flash of light is passed through it. The light (which passes simultaneously through all parts of the film frame) is focused on the sensitive surface of a storage-type camera, such as the iconoscope. The light flashes are timed to occur during the intervals between successive field scans, that is, while the extinguished scanning spot is moving from bottom to top of the frame. The light is strong enough to produce an intense electrical image in the tube during this brief period. The electrical image is stored and is scanned during the next scanning field, producing the picture signal for that field. Light is again admitted between fields and the stored image scanned thereupon by the second field. When one film frame has been thus scanned, it is pulled down by a claw mechanism and the next frame takes its place.

In Europe and other areas where the television scanning rate is 25 picture scans per second, the custom is to operate intermittent projectors also at 25 frames per second, or about 4% faster than the intended film projection rate of 24 frames per second. The corresponding increases in speed of motion and sound pitch are not so great as to introduce unacceptable degradations of the performance. In the U.S. and other areas where television scanning occurs at 30 frames per second, it is not feasible to run the film projector at 30 film frames per second, since this would introduce speed and pitch errors of 25%. Fortunately, a small common factor, 6, relates the scan rate of 30 and the film projection rate of 24 frames per second. That is, four film frames consume the same time ( $\frac{4}{24} = \frac{1}{6}$  sec.) as five scanning patterns ( $\frac{5}{30} = \frac{1}{6}$  sec.). Thus, if four film frames pass through the projector while five picture scans are completed, both the film motion and the scanning proceed at the standard rates. The two functions are kept in step by holding one film frame for three scanning frames, the next frame for two scans, the next for three scans and so on.

Recording of television programs on film involves similar techniques, but in reverse. The television image to be recorded is reproduced at high brilliance on a high-quality monitor picture tube having a phosphor producing highly actinic light. The television image is focused optically on film in a special form of motion-picture camera, which in effect discards six television scans per second, thus yielding a recording at the standard film rate of 24 frames per second. The extra time thus made available is used to move the film from frame to frame in the camera. The aberrations and halation of the high-brightness picture tube, compounded with the imperfections of scanning, film exposure and processing, make the quality of television film records (kinescopes or "kines") substantially poorer than that of films made by direct photography of the same subject matter. The degradation is evident on home receivers during rebroadcast of kinescope recordings.

Most television program recording is done on magnetic tape. This technique produces rebroadcast programs which, when the equipment is in good adjustment, are virtually indistinguishable from the original broadcast. The magnetic tape, 2 in. wide, is moved at 15 in. per second past a magnetic recording head which rotates across the width of the tape, imposing on it a series of crosswise magnetic line patterns which correspond to the lines of the scanning pattern. To keep the pickup and tape motions closely identical during recording and playback, index signals are imposed during recording and these are used to control the drive motors during playback. The television signal is recorded by frequency modulation on a carrier signal, thus avoiding the difficult problem of direct recording at the extremely low frequencies (30 c.p.s. and less) present in the picture signal itself.

Magnetic video recording is widely used in broadcast operations, not only because of its high quality but because it is immediately available (without subsequent processing) for playback. In the U.S. many of the network programs broadcast in and west of Chicago are derived from magnetic recordings, stored for an hour or more after their release along the eastern seaboard to allow for the difference in time in western cities. Recording of colour programs is also possible on magnetic tape, but in the mid-1960s it was still subject to somewhat lower quality than black-and-white recording, since the necessary precision of tape transport and pickup rotation is greater in the colour system. See also TAPE RECORDING, MAGNETIC.

### VI. TELEVISION BROADCASTING

The methods and equipment employed in television broadcasting follow the basic principles outlined above, but differ in detail according to the nature of the program source; i.e., the studio, film or a point remote from the studio.

**1. Studio Programs.**—Television studios, like those for sound broadcasting, are designed with acoustical properties which produce a "live" sound without noticeable reverberation. The studio must also possess a comprehensive system of lighting, capable of creating uniform illumination of several hundred to a thousand foot-candles for monochrome productions.

BY COURTESY OF (ABOVE) WNBC, NATIONAL BROADCASTING COMPANY, CHICAGO, (TOP RIGHT) NATIONAL BROADCASTING COMPANY, NEW YORK, (BOTTOM RIGHT) COLUMBIA BROADCASTING SYSTEM

**TELEVISION BROADCASTING:** (Above) A film camera chain that adapts photographic film for television transmission. It consists of 16- and 35-mm. projectors, a slide projector, a multiplexer for transmitting the three kinds of film in combination, and a monitor. (Top right) A television program in production. The centre camera is mounted on a crane dolly for vertical movement. (Bottom right) A television studio monitoring booth. The program director, technical director, and lighting director oversee the on-the-air picture on the large monitor and preview the pictures to follow on the smaller monitors

For colour programs, two to three times as much light is required to overcome the losses in the mirrors and filters within the camera. In addition to general lighting, localized lighting fixtures ("scoops" and spotlights) are used to emphasize the centre of interest, for modeling of facial contours and the like. A ventilating system capable of removing the heat generated by the lighting system without noise must be provided and air conditioning may be needed if the lighting system is to be used for extended periods in the summer months.

The cameras and microphones are mounted so that they can follow the action on the set. The camera usually is carried on a dolly equipped with smooth-rolling wheels and is mounted on an elevating and training stand which permits the camera operator to achieve the desired angle and position relative to the action. The microphone is mounted on a boom or long arm which can position the microphone above the action, just out of view of the camera. The floor crew (camera operator, a man to assist the operator in moving the camera dolly, the microphone boom operator and the director's floor assistant) are equipped with earphones through which instructions are relayed from the control room.

Studio scenery for television productions is generally simpler than that used in motion-picture production. Since the production occurs in "real time" the cameras must be strictly coordinated with the action and must move from one set to another, on the floor of a single studio, as the presentation proceeds. In live broadcasts, retakes cannot be made, and close co-ordination of camera and microphone action with the script must be achieved in rehearsal.

Control of the camera is achieved in part by telephoned instructions from the control room, but the main reliance for correct composition and focus is placed on the cameraman, who views the picture picked up by his camera on an electronic view finder. This is a compact picture monitor connected to the camera tube. The camera is usually equipped with a lens turret containing as many as four lenses of different focal lengths. The turret is rotated by the camera operator (while the camera is not in action) to bring into play the lens having the focal length appropriate for the desired

area of the set. The lenses are similar to those used in 35-mm. professional motion-picture cameras, with maximum apertures of the order of  $f/4.5$  to  $f/3.5$ . Small apertures are used wherever possible to secure the necessary depth of focus.

**2. Film Broadcasting.**—To permit uninterrupted programming, two film projectors are needed, one of which is being readied for the next reel while the other is on the air. A single camera tube may accept images from either of the projectors by use of a mirror set at  $45^\circ$  to the respective optic axes (fig. 29). The picture and sound signals produced by film equipment are viewed and auditioned on monitors and are adjusted by video- and audio-control operators, as in studio productions. When an iconoscope camera tube is used, the video-control operator must adjust special controls to minimize the flare and uneven shading to which this type of tube is subject.

Televising colour film requires that the coloured image be broken up into three primary-colour images, as in the studio camera for colour productions (fig. 24).

Vidicon camera tubes or flying spot cameras are used.

**3. Outside Broadcasts.**—To televise sporting events and other programs at locations remote from the studio, portable equipment is used. This includes cameras, microphones and several units which house the control and switching system, monitors and the synchronization generator. The portable synchronization unit, which performs all the functions of the more elaborate generators permanently installed in the studio building, must meet rigid standards since it must correctly control the scanning of millions of receivers and is often dependent on uncertain power sources at remote locations.

Remote broadcast signals may be fed directly into a network connection, but more usually they are transmitted to the associated station by a microwave radio system. This comprises a low-power transmitter operating at a frequency in the vicinity of 2,000 or 7,000 mc., using frequency modulation for the picture transmission and a receiver at the studio or transmitting station. At these extremely high frequencies, a highly directive radio beam may be produced by reflecting the radio waves from a paraboloid surface ("dish" antenna) of modest size. The radio energy is thereby so concentrated that a transmitter power of less than one watt is capable of covering distances of 10 to 20 mi. so long as the path from transmitter to receiver is unobstructed.

**FIG. 29.**—ARRANGEMENT FOR USING EITHER OF TWO FILM PROJECTORS WITH ONE CAMERA TUBE

**4. Networks.**—National distribution of major television programs is achieved through a comprehensive common-carrier network system. Three types of facilities are used. Within a given city, special telephone lines ("video pair" circuits) are provided; these are specially equalized to provide uniform transmission over the wide band of frequencies occupied by the picture signal.

For intercity connections, coaxial cables were once widely used, although these were largely replaced by the microwave relay system. The coaxial cable consists of two electrical conductors, a hollow sheath and a wire located concentrically within it. This configuration of conductors is capable of transmitting a wide band of frequencies without discrimination over a distance of several miles. At intervals of about eight miles, video amplifier repeaters restore the signal energy lost in the preceding section of cable. The early coaxial cable network in the U.S. was limited to a maximum frequency range of about 2.7 mc., substantially less than the 4-mc. maximum actually present in the picture signal. Later coaxial cable installations, with repeater amplifiers every four miles, could handle a maximum frequency range of nearly 8 mc.

Major reliance for television network transmission in the U.S. is placed on the microwave relay system. This consists of a large number of relay stations (over 100 are needed to span the country) operating in the vicinity of 4,000 mc. Highly directive transmitting and receiving antennas, mounted on towers in exposed locations at intervals of about 25 mi., receive and retransmit to the next relay station a frequency-modulated picture signal.

**5. Transoceanic Broadcasts.**—The initial attempt to interconnect the television networks of Europe and North America came in 1962, when the American Telephone and Telegraph company used its artificial satellite, called Telstar, to relay television signals between Andover, Me., Goonhilly Downs, Cornwall, Eng., and Pleumeur-Bodou, Brittany, France. The first transmission, of a

purely experimental nature, originated in the U.S. on July 10, 1962, and this was followed the next day by transmissions to the U.S. from France and England; the first colour transmission occurred on July 16. Reception was limited to about 15 min. the period during which the satellite was within sight of the sending and receiving stations. To maintain continuous transmissions, the planners of the system proposed using a series of satellites, so that at least one would always be in position to relay signals. An alternate proposal called for a single relay satellite in a "stationary" orbit, so adjusted that it would remain always above the same point on the surface of the Earth. The first public demonstration of this system was on Oct. 10, 1964, when television coverage of the opening ceremonies of the Olympic games was relayed from Tokyo to North America via a Syncom satellite positioned above the Pacific ocean. See also BROADCASTING.

## VII. CLOSED-CIRCUIT TELEVISION

The term closed-circuit television, which originally meant a local system consisting of a camera and several monitor receivers connected by a coaxial cable, came to refer to any system, however extensive, in which the televised subject matter is intended for the organization that owns or has hired the system for its exclusive use, as against broadcasting or other general use by the public. Such systems are widely used in industry and commerce and for educational purposes. They range from a single camera and monitor installed in a steam plant to monitor flame condition or water level to a nationwide network hired on a single-occasion basis (e.g., by an automobile manufacturer to present information on new models to dealers assembled in theatres having projection television equipment). Coaxial cable is used in local installations, but microwave relay systems identical to those used in broadcasting may be employed for large closed-circuit hookups.

Since a closed-circuit system is entirely under the control of its proprietor and is not intended to serve the general public, it is possible to employ scanning standards which differ from those used in broadcasting. Advantage of this freedom in system design is taken in the so-called slow-scan closed-circuit system, which is used to transmit signature records and balances in banks, for example.

In the typical slow-scan system, the pictures may be scanned at a rate as slow as one picture every three seconds, with a scanning pattern of 180 lines per picture. The maximum frequency in the picture signal then reaches only 3,000 c.p.s., which can be transmitted inexpensively; i.e., over ordinary telephone lines. In the majority of closed-circuit systems for industry, education and theater projection; however, the image-quality requirements are essentially identical to those of broadcasting, so the broadcast standards are used.

**1. Equipment.**—Equipment for closed-circuit television is similar to but generally less elaborate than that used for broadcast purposes. The Vidicon camera tube is used in industrial television almost to the exclusion of other types, since it is less expensive than the other types and more suitable for compact cam-

(TOP LEFT, RIGHT) MOTOROLA INC., (BOTTOM LEFT) BOARD OF EDUCATION, CITY OF CHICAGO, (BOTTOM RIGHT) RADIO CORPORATION OF AMERICA

**APPLICATIONS OF TELEVISION:** (Top left) An eight-inch-diameter transistorized camera being used to probe underground conditions to aid in rescuing trapped miners. (Top right) Police officers coordinating traffic by means of closed-circuit television combined with two-way radio dispatch facilities. (Bottom left) Closed-circuit television makes it possible for the special skills of teachers to be shared by larger audiences of students. (Bottom right) An experimental camera designed to transmit picture of astronauts en route to the moon

eras. In educational television, however, image orthicon tubes and associated equipment very similar to broadcast-station units are widely used. Since closed-circuit installations in industry are seldom operated by television specialists, care must be taken in equipment design to make operation and maintenance simple. An important industrial use is in viewing remote or hazardous events in which it is inconvenient or unsafe to have an operator directly in attendance at the camera. For such purposes, controls for remote operation of the camera, including adjustment of lens aperture and focus, are provided.

**2. Applications in Education.**—Educational television is often conducted on a public-broadcast basis in cities where a channel is available for this purpose and where the expense of the transmitting station can be borne. The simpler and less costly closed-circuit system found increasing favour with educators, however, particularly in larger institutions and in medical schools, where the whole installation can be confined to one building or a few neighbouring buildings.

In education, television's most impressive use is extending the range of a gifted teacher beyond a single classroom. When a broadcast system is available, pupils in many schools may be taught simultaneously by a particularly able teacher prior to a more personal instruction and discussion of the subject matter in individual classes with a local teacher in attendance. While motion pictures may also be used in this way, the televised image commands the pupils' attention to a far greater extent than does film projection. Even when film is used as a program source, the psychological impression on the student is heightened.

Television is also an important teaching aid in bringing to a number of students simultaneously the details of an experiment or operation which otherwise could be viewed only by a single person or small group. Examples include viewing through a microscope and bringing medical students directly into visual contact with operating procedures without interfering with those performing the operation. Use of closed-circuit television for instruction in surgical procedures is widespread; elaborate colour-television installations have been made in medical schools and hospitals, colour being an important adjunct in delineating diagnosis and procedure. An important advantage of television in such instruction is that the final outcome is not known as the demonstration proceeds and this lends an air of expectancy which is lacking when colour motion pictures are used for the same purpose.

**3. Industrial Applications.**—One of the first uses of closed-circuit television in industry was an installation of boilerwater-level monitors at the Hell Gate electric generating station in New York, made directly after World War II. This application later was extended to the monitoring of flames in burners and smoke issuing from stacks. Here the justification for television, as against photographic methods, is the need for immediate information without the delay of film processing. Other applications involve the safe handling of nuclear materials, jet fuels and other hazardous substances. A stereoscopic form of television, comprising two complete systems which present two images separately to the two eyes of the operator, has been used in conjunction with precise remote-handling equipment for packing radioactive substances, disposing of radioactive wastes and the like. The ability of the television camera to operate in situations unfriendly to human observers (as outside the fuselage of an airplane in flight, to observe operation of landing gear during engineering tests) also accounts for increasing usage in industry.

The radiation hazard brought industrial television into play in X-ray technology. A fluoroscope or other device for translating X-ray intensities into visible light is viewed by a sensitive television camera and the image brought out at a safe distance from the exposure site. Here, again, motion-picture photography might be used, but the television system permits immediate observation without processing delays and avoids the cost of film and processing which might, in the course of a year, outweigh the cost of a simple television system.

Television systems may also be used for surveillance, particularly to assist guards in patrolling restricted areas. Another surveillance application is in reading numbers on freight cars in

railway switchyards to aid the yardmaster in making up trains.

**4. Commercial Applications.**—The primary application of closed-circuit television in commerce, as contrasted with industry, is remote inspection of records in banks and other institutions. In one installation, four branches of a bank were connected with 12 mi. of coaxial cable to permit any teller to call for the signature card or the current balance of any depositor from a central bookkeeping department. Although the initial and maintenance costs of such a system were substantial, the speed and accuracy with which doubtful accounts may be checked justified the use of the system. Extension of this technique to remote reading of blueprints and other records depended upon lowering the cost of interconnecting cables and increasing the detail of images so that, for example, a full 8½ by 11-in. page of typewritten material could be read on a monitor without error.

Techniques akin to those of television are finding increased use in other commercial and industrial fields. One application is a scanning technique whereby printed characters are "read" and identified by comparing the character with each of a series of standard templates or matrices. This may be done by storing the video signal arising from scanning in a memory array in the form of voltages which may be compared with a similar array of voltages in a matrix corresponding to each letter or number to be recognized. Either mechanical or electronic scanning may be used in this technique. See also references under "Television" in the Index.

**TELFORD, THOMAS** (1757–1834), Scottish architect and civil engineer renowned for his building of roads and bridges, was born near Westerkirk in Eskdale, Dumfriesshire, on Aug. 9, 1757, the son of a shepherd. After apprenticeship to a stonemason in Langholm, he worked as a journeyman mason in Eskdale and Edinburgh until 1782, when he traveled to London and was employed in building Somerset house under Sir William Chambers. At this time his ambition was to become an architect and his self-education was directed to this end. After a brief period of employment at Portsmouth his patron, William Pulteney, obtained for him the post of surveyor of Shropshire in 1786. While so engaged, Telford built churches at Bridgnorth and Madeley, rebuilt the county jail, excavated the ruins of Uriconium (mod. Wroxeter) and constructed many bridges, including three over the river Severn at Montford, Buildwas and Bewdley, the second being of iron.

In 1793 Telford was appointed agent and engineer to the Ellesmere Canal company and forsook architecture for engineering. His two great aqueducts which carry this canal over the Ceiriog and Dee valleys at Chirk and Pont Cysylltau showed him to be a master of the structural use of cast iron and brought him national fame. In 1803 he was employed by the government on a development scheme for the Scottish Highlands, where he was responsible for the Caledonian canal, harbour works at Aberdeen, Dundee and elsewhere and the building of over 900 mi. of roads, including many bridges. Telford was next engaged on the improvement of the roads from Chester and Shrewsbury to Holyhead in the course of which he built his two famous suspension bridges over the river Conway and the Menai straits. The threat of railway competition induced canal companies to employ him to carry out improvement works which included a new tunnel at Harecastle, Staffordshire, on the Trent and Mersey canal, the improvement of the Birmingham canal and the construction of a new canal from Wolverhampton to Nantwich. Among Telford's other works were the Göta canal in Sweden, St. Katherine's dock, London, roads in the Scottish lowlands and the bridges over the Severn at Tewkesbury and Gloucester. On the invitation of the founders, Telford became first president of the Institution of Civil Engineers, the growth of which was largely due to his efforts and prestige. He died in London on Sept. 2, 1834.

**TELL, WILLIAM**, Swiss hero who, like Robin Hood, symbolizes the struggle for political and individual freedom. Historically, the existence of Tell is disputed, at least since the 19th century; but as a legendary figure he has always enjoyed enormous popularity.

According to popular legend, Tell was a peasant from Bürglen, a small village in the canton of Uri, where he lived in the 13th and early 14th centuries. One day he came with his son to Altdorf, to find that the Austrian governor (Gessler) had had a hat placed on a stake in the main square as a symbol of Austria's sovereign power. Each passerby was expected to bow in front of this hat, but Tell was too proud to do so, and as a penalty he was compelled by Gessler to test his marksmanship by shooting with his crossbow an apple from his little son's head. To Gessler's amazement, Tell succeeded, but as he had threatened the governor—saying that his second arrow was destined for Gessler's heart—he was arrested and put on a boat to be taken to Gessler's castle at the northern end of Lake Lucerne. During the journey a great storm arose, and, as Tell was an expert helmsman, he was freed so that he might steer the boat to safety. But when the boat came near the shore, he seized his bow and escaped by a bold leap ashore. As a final act of defiance and revenge, he later killed Gessler from an ambush in the "Hohle Gasse" ("Hollow Way"), near Küssnacht. This deed, together with other events (such as the signing of the secret covenant of the confederates in the meadow of Rütli, in 1291), was the signal for the rise of the people against Austrian rule (see SWITZERLAND: History).

The origins of this legend are obscure, and early chronicles, which deal with the misdeeds of the Austrian governors, fail to mention Tell. The first evidential basis for the Tell story is contained in two 15th-century texts: a song of c. 1477 (containing a fragment of an older "Tellenlied" no longer extant), and a chronicle of c. 1470 (in the so-called *Weisse Buch von Sarnen*). The song gives a mutilated account of the apple scene, only hints at the rest of the story, and extols Tell as the first Swiss confederate; one feature of the song—that Tell is threatened with death if he misses his target—is missing from the chronicle. The chronicle tells of the cruel deeds of the governors and links "Tall," as he is called here, with the Rütli covenanters. Subsequent versions are all combinations or elaborations of these two texts. With the 16th-century chronicle *Chronicon Helveticum* (published 1734–36) of Gilg Tschudi (q.v.)—which generally rounds off the tale, giving, for example, November 1307 as the date of Tell's deeds and New Year 1308 as the date of Switzerland's liberation—the story finds its classic form. Tschudi's account was for a long time definitive and was the main source of Schiller's *Wilhelm Tell* (1804), the stirring play that gave the tale worldwide renown.

It is evident from the transmission of the Tell story that its rise and development are popular rather than historical. But, although 19th-century historians (e.g., J. E. Kopp) and later critics have shown that many so-called historical chronicles—including the *Weisse Buch* and especially Tschudi's—are defective and unreliable, there is still no conclusive evidence for or against Tell's existence, and it may simply be that some of the deeds attributed to him have been culled from other heroic figures or mythical sources. Because marksmanship is a central feature, not only of the extant texts of the Tell legend but also of other legends, scholars have been led to perceive relationships. For instance, William Cloudeley in Britain, Egill (or Eigil) in Scandinavia, and Henning Wulff (or Wulffen) in Germany are all found to share similarities with Tell. It is thought that they may all derive from a 10th-century Norwegian prototype. Nearest to the Swiss tradition—especially the "Tellenlied"—is the story of the marksman Toko, as told in the Danish chronicle of Saxo Grammaticus (c. 1200). However, it is not clear how the saga may have reached Switzerland. Perhaps it was introduced by 15th-century Humanists in an attempt to find a story for the origins of the Confederation that would appeal to the growing Swiss national conscious-

ness; certainly the contemporary fanciful chronicle *Vom Herkommen der Schwyzer und Oberhasler* points in a similar direction by giving the confederates Swedish and Frisian ancestry.

Whatever its origin and authenticity, the legend of William Tell has been a constant and powerful source of artistic inspiration. The theme of Tell has been treated by composers (e.g., André Grétry and Rossini) and artists (e.g., J. H. Füssli [Henry Fuseli] and Ferdinand Hodler), as well as poets and dramatists. It plays an important part also in the Swiss popular theatre, from the time of the Uri play (the so-called *Uerner Tellenspiel*) of c. 1512 to the 20th-century productions at Altdorf and Interlaken. The myth is still vital, and there has been a continued popularization of the tale both in the cinema and in television.

In the course of time the figure of Tell has taken on various forms and meanings: 15th-century Humanists, for example, regarded him as the Swiss Brutus, a national hero who embodied the principles of moral freedom; in 18th-century France he became the much-cited champion of the rights of man and an idol of the Revolution. At all events, Tell's significance—in Switzerland and beyond—lies less in a disputed historical fact than in the mighty power that he represents as an exponent of the age-old passion for freedom.

**TELL EL AMARNA** (TALL AL AMARNA), the modern name given to the collection of ruins and rock tombs in upper Egypt, on the east bank of the Nile, 58 mi. (93 km.) by river below Asyut and 190 mi. above Cairo. The ruins are those of Akhetaton, the city built about 1375 B.C. by Ikhnaton (Amenhotep IV) as the new capital of his kingdom (in place of Thebes) when he abandoned the worship of Amon and devoted himself to that of the Aton; i.e., the solar disk. Shortly after Ikhnaton's death the court returned to Thebes, and the city, after an existence of hardly more than 15 years, was abandoned (see IKHNATON).

Tell el Amarna is of great interest not only because of its association with the revolutionary Pharaoh Ikhnaton but also because it is one of the few city sites of ancient Egypt that has been carefully excavated. The first scientific clearing of the site was undertaken by Sir Flinders Petrie in 1891–92, and in succeeding years both British and German archaeologists unearthed the ruins of the city, which extended along the Nile for a distance of five miles. Because Ikhnaton chose a virgin site for his capital and because of the relatively short duration of its occupancy the excavators could reconstruct an accurate picture of the layout of the city.

When Ikhnaton ordered the founding of the city in the fourth year of his reign, he had stelae (inscribed tablets) carved in the cliffs at the end of the desert to demarcate the city limits. Although the city as a whole displays little in the way of town planning, the major official quarters at its centre were carefully organized. Running north and south throughout the entire length of Akhetaton was the Royal road, on either side of which were the principal buildings. The largest of these was the Great temple of the Aton, the enclosure wall of which was nearly  $\frac{1}{2}$  mi. long and 300 yd. broad. The temple consisted primarily of a series of walled courts separated by towered gateways leading eastward to the main sanctuary, which was completely in the open air. An elevated platform in the centre of this final court served as the high altar to the sun-god. Throughout the length of the temple and

also outside its walls were numerous offering tables of stone and mud brick. The open character of the cult of the Aton stood in contrast to that of the Theban Amon, whose worship had been carried on in the dimly lighted innermost chambers of his temple.

South of the Great temple were situated the buildings for Ikhnaton's use. On the east side of the Royal road was the commodious residence of the royal family, provided with terraced gardens, while directly across the road was the official palace, where the affairs of state were carried on. Both these buildings, as indeed most of the dwellings at Tell el Amarna, were constructed principally of mud brick, baked in the sun. Stone was sparingly used for such architectural elements as columns and doorways. Many of the rooms of these complex royal buildings had walls, floors and ceilings painted in a lively naturalistic style. Such scenes as those depicting the intimate family life of Ikhnaton from his living quarters are among the masterpieces of Egyptian art. A bridge, spanning the Royal road, joined the two buildings and provided a place where the king might appear publicly to reward his nobles with gifts of gold. A second smaller temple to the Aton, similar in plan to the Great temple, lay immediately to the south of the king's residence.

Two other buildings from the central city are important as sources of major archaeological finds. In the house of the sculptor Thutmose were discovered many of the masterworks of Amarna sculpture, notably the portraits of Queen Nefertiti. In 1887 the chance diggings of a peasant woman in the records office brought to light a store of approximately 300 clay tablets inscribed in the cuneiform script. From these tablets, written by the vassal princes of the Egyptian empire in Syria and Palestine, as well as by the kings of Babylonia, Assyria and Mitanni, to Amenhotep III and his son Ikhnaton, it is possible to trace the decline of the Egyptian empire of the 18th dynasty. Ikhnaton, who was deeply preoccupied with religious matters at Akhetaton, had a corresponding lack of interest in foreign affairs.

Unlike Thebes, where crowded conditions had forced the construction of multistoried houses, the dwellings at Akhetaton had only one floor. The nobles possessed spacious villas with landscaped gardens. A small shrine open to the sky for the worship of the Aton was one of the distinctive features of such an estate. Generally the bedrooms and other rooms surrounded a central living room, the roof of which was higher than that of the rest of the house, thus permitting clerestory lighting and ventilation. The workers were lodged in simple cottages lined next to one another in rows.

Toward the end of Ikhnaton's reign there is evidence of his desire to seek a possible reconciliation with the old priestly hierarchy of Thebes. At about the same time a rift between Ikhnaton and his wife, Queen Nefertiti, developed; the queen retired to the north part of Tell el Amarna, where a special palace was constructed for her use. The archaeological evidence from this quarter suggests that she was an ardent supporter of the Aton religion.

In the desert hills to the east were hewn the tombs of the important officials. These tombs resemble those at Thebes in having an exterior forecourt, an entrance hall sometimes provided with columns, and a second hall at the rear of which was a small room containing a statue of the tomb owner. These chambers were accessible for the funerary cult; the burial shaft generally descends from the floor of the first hall, but in none of the tombs has any burial been discovered. Although the work in decorating the tomb chapels was often hastily and incompletely carried out, the painted reliefs of these tombs have been a major source of information regarding the daily life and religion of Akhetaton. The representations of various buildings of Tell el Amarna that appear on the walls have been valuable aids to the excavators in interpreting the often meagre architectural traces surviving in the actual city, particularly of the Great temple, which was razed to the ground by the opponents of the Aton religion after Ikhnaton's death. In these tombs the emphasis is upon the activities of the owner in Akhetaton rather than the life after death. In a number of the tombs have been found versions of the hymn to the Aton, in which is described the universality of the sun-god as creator and sustainer of all life. The reliefs are in an unconventional,

often exaggerated style, tending to reflect a momentary and emotional aspect rather than the static mood that had characterized Egyptian art previously. The tomb of Ikhnaton and his family is situated in the side of a dry watercourse about 4 mi. E. of the city. It contains an unprecedented scene of the royal family in mourning over the death of the princess Meketaton, who was buried in a section of the tomb. There is no certain evidence, however, that either Ikhnaton or his wife was ever interred there.

The return of the court to Thebes after Ikhnaton's death must have been rather sudden, since houses under construction in the northern sector of the city were abandoned before completion. The reform in religion and art that Ikhnaton had sought to effect ended in failure, for the number of faithful adherents was relatively small. Even at Tell el Amarna itself in the homes of the workers were discovered figures and names of the gods of the older tradition. After the Pharaoh died, a number of his retainers found it more convenient to adapt themselves to life at Thebes rather than support a lost cause at Akhetaton. See also references under "Tell el Amarna" in the Index.

**TELLICHERRY**, a town and seaport in the Cannanore District of Kerala, India, lies 42 mi. (68 km.) N of Kozhikode (Calicut). Pop. (1961) 44,763. On a group of low wooded hills running out to the sea, it is protected by a natural breakwater of basalt rocks. To the north of the town is a small river (14 mi. [23 km.] long), which is, however, navigable only for 3 mi. Tellicherry is the seat of Brennen College (founded 1862), with about 700 students. There is also a flourishing furniture industry. It is the chief outlet for pepper grown in the surrounding region, for coffee and sandalwood from the Western Ghats, and for coconuts grown all along the Malabar Coast. In 1683 the British East India Company established a factory at Tellicherry on a site formerly occupied by a French mud fort. It was the company's first major trading post on the Malabar Coast, and it became important as an entrepôt for pepper.

(G. KN.)

**TELLURIUM**, a brittle, silvery-white metallic chemical element. It is the third member of the sulfur family (symbol Te, atomic number 52, atomic weight 127.60).

In 1782 F. J. Müller von Reichenstein, in examining Transylvanian gold minerals, suspected the presence of a new element and called it *metallum problematicum* or *aurum paradoxum*. In 1798 M. H. Klaproth extracted tellurium from white gold ore, named it, and established its identity as differing from antimony, with which it had been confused. It was not until 1832 that J. J. Berzelius made a careful study of the chemistry of the element.

**Occurrence.**—Although widely distributed, tellurium has an estimated percentage in the earth's crust of only  $10^{-9}$ . Rarely found as native tellurium, it commonly occurs as tellurides of copper, lead, silver, gold, iron, and bismuth. Typical minerals are sylvanite,  $(\text{AuAg})\text{Te}_4$ ; calaverite,  $\text{AuTe}_2$ ; muthmannite,  $(\text{AuAg})\text{Te}$ ; krennerite,  $(\text{AuTe}_2)_2$ ; petzite,  $(\text{Ag}_3\text{AuTe}_2)_2$ ; tetradymite,  $\text{Bi}_2\text{Te}_2\text{S}$ ; rickardite,  $\text{Cu}_4\text{Te}_3$ ; melonite,  $\text{NiTe}_2$ ; and altaite,  $\text{PbTe}$ . Less common are the tellurites, telluric ochre,  $\text{TeO}_2$ , durdenite,  $\text{Fe}_2(\text{TeO}_3)_3 \cdot 4\text{H}_2\text{O}$ , and tellurates as montanite,  $\text{Bi}(\text{OH})_2\text{TeO}_4$ , and ferrotellurate,  $\text{FeTeO}_4$ . The tellurides occur with the sulfides of copper, silver, gold, and nickel. Red tellurium sulfur of Japan contains 99.76% S, 0.17% Te, 0.06% Se, and 0.01% As. Tellurium minerals are found in the United States, Canada, Mexico, South America, Sweden, central Europe, Zambia, the U.S.S.R., and Japan. The chief sources of tellurium are the slimes from copper and lead refineries and flue dusts from processing of telluride gold ores.

**Uses.**—Although comparatively large supplies of tellurium are available, no single use has been developed that creates large demand for this element. Early attempts to use tellurium in metallurgical products seemed to indicate that the addition of tellurium to the alloys of aluminum, tin, certain steels, and cast iron gave undesirable properties. Apparently too much was added, for it has been reported that small concentrations of tellurium in alumi-

num alloys increase ductility, in tin alloys increase the hardness and tensile strength, and in stainless steels increase the machinability. Appreciable increase in the depth of chill in iron (see CAST IRON) can be obtained by addition of minute amounts of tellurium. The addition of 0.05% Te to lead increases its resistance to corrosion. In manganese-magnesium alloys tellurium increases resistance to corrosion. Tellurium has been used as a brightener in certain plating baths. A beryllium-copper-tellurium alloy has been reported. Selenium and tellurium in copper or copper-rich alloys improve machinability without producing so-called hot shortness. Both are used in preference to sulfur.

In alloys like Babbitt metal addition of tellurium refines the grain structure, aids casting, and improves physical properties at high temperatures. Tellurium in hydrogenation and cracking catalysts used for conversion of heavy oils to motor fuels reduces carbon formation. The addition of 0.1 to 2% tellurium in rubber compounding improves resistance to heat, oxidation, and abrasion and increases resiliency. Some organic tellurium compounds have germicidal properties, and diethyl telluride possesses antiknock characteristics. This latter use has not been important, since it is accompanied by a disagreeable odour. Zinc tellurite has been patented as an antifouling paint. Tellurium has been used to a limited extent in colouring glass or porcelain, large colloidal particles giving a blue colour, small particles a brown colour, and telluride a red to red-violet colour. Acid solutions of dioxide have been used as a dip for silver ornaments, giving a "platinum finish" to the metal. Soluble tellurium compounds are used in toning baths in photography. As little as only one micromole of tellurium taken into the human body gives the breath a penetrating garlic-like odour, which may appear in less than half an hour after ingestion; it is reported that 2 g. of tellurium as sodium tellurite may be a lethal dose. The use of colloidal tellurium as a fungicide and insecticide in wood preservation has been reported.

An extremely diverse group of articles has been published in technical journals on such topics as effect of tellurites on pyruvic dehydrogenase, catalyst in Kjeldahl digestion, effect on electrodes for the electrolysis of sodium chloride, grain growth of chromium steel, effect on hydrogen absorption by steel, effect on iron carbonyl, tellurites as poisons for enzymes, solution of tellurium mirrors by free radicals, and the catalytic hydrogenation of shale oils. However, no new use was reported that would contribute to large-scale consumption of tellurium or its compounds.

**Methods of Production.**—The crude copper anodes used in the electrolytic refining of copper contain a high percentage of selenium and tellurium that was present in the ore. Upon electrolysis of the copper, the selenium and tellurium and other valuable elements (gold and silver) settle in the electrolyte as anode mud. Although procedures for the recovery of tellurium are not identical in this and other types of residues, the general principles include fusion with sodium carbonate and nitrate or extraction with sodium hydroxide, neutralization of the water solution of sodium tellurite to form precipitated tellurium dioxide, and, finally, dry reduction of the tellurium dioxide by means of a mixture of flour and borax to form molten tellurium. An alternative method includes solution of the dioxide in hydrochloric acid and reduction with sulfur dioxide to form precipitated tellurium. Tellurium appears on the market in the form of bars, as ground crystalline tellurium, or as dry precipitated powder. Some tellurium has been redissolved in nitric acid (specific gravity 1.2) and crystallized as basic nitrate.

**Properties.**—Tellurium is a complex element, having 22 known isotopes (in the 1960s) with mass numbers ranging from 114 to 135 (see ISOTOPE; NUCLEUS: *Chart of Properties of the Nuclides*).

Tellurium has a density of 6.24; it melts at 449.8° C and boils at 1,390° C; its hardness is 2.3 (Mohs). It crystallizes in hexagonal-rhombohedral prisms and is isomorphous with the stable gray modification of selenium. Its allotropy is less well defined than that of either selenium or sulfur. It was presumed that amorphous and crystalline modifications of tellurium existed. X-ray diffraction has shown that precipitated tellurium is not amorphous but crystalline (hexagonal). Colloidal preparations are easily made by reducing dilute solutions of telluric acid with hydrazine

or sulfurous acid, with or without protective colloids. Alpha-particle bombardment of tellurium produces  $\text{Xe}^{133}$ . The vapour of tellurium at the boiling point is diatomic  $\text{Te}_2$ . Tellurium-vapour lamps also containing mercury provide almost a continuous spectrum that approaches the characteristics of daylight. Transmission is in the red (7,200–5,950 Å) 14.5%, yellow (5,950–5,650 Å) 22.5%, green (5,650–4,950 Å) 56%, and blue (4,950–4,000 Å) 7%.

Tellurium occurs in Group VI of the periodic system with oxygen, sulfur, and selenium. In the second long series of 18 elements, it lies between antimony and iodine. Although strongly electronegative, tellurium is less so than selenium, sulfur, or oxygen. Tellurium exhibits valence states of  $-2$ ,  $+2$ ,  $+4$ , and  $+6$ . These are illustrated by  $(-2)$  hydrogen telluride and the tellurides;  $(+2)$  tellurium monoxide and tellurium dichloride;  $(+4)$  tellurium dioxide, tellurous acid, the tellurites, and the tetra halides;  $(+6)$  tellurium trioxide, telluric acid, the tellurates, and the hexafluorides.

**Compounds.**—Hydrogen telluride ( $\text{H}_2\text{Te}$ ) is prepared by the action of hydrochloric acid on aluminum or magnesium telluride or by action of water on aluminum telluride ( $\text{Al}_2\text{Te}_3$ ). Pure  $\text{H}_2\text{Te}$  is reasonably stable, but dry or moist it reacts readily with oxygen to form elemental tellurium and water. Both melting and boiling points of  $\text{H}_2\text{Te}$  are lower than those of water, and  $\text{H}_2\text{Te}$  is less polar. Its solubility in water is at least 0.09 moles per litre at atmospheric pressure. Hydrogen telluride is both a stronger reducing agent and a stronger acid than either hydrogen sulfide or hydrogen selenide. The respective constants for the primary ionization of  $\text{H}_2\text{S}$ ,  $\text{H}_2\text{Se}$ , and  $\text{H}_2\text{Te}$  are  $1.15 \times 10^{-7}$ ,  $1.88 \times 10^{-4}$ , and  $2.27 \times 10^{-8}$ . Like  $\text{H}_2\text{S}$  and  $\text{H}_2\text{Se}$ ,  $\text{H}_2\text{Te}$  has a very disagreeable odour and is very toxic. Sodium telluride ( $\text{Na}_2\text{Te}$ ) is prepared by a direct combination of sodium and tellurium in liquid ammonia; an appropriate excess of tellurium dissolves the precipitated  $\text{Na}_2\text{Te}$  and yields a polytelluride (e.g.,  $\text{Na}_2\text{Te}_2$  or  $\text{Na}_2\text{Te}_3$ ). Hydrogen telluride may be added to aqueous solutions of sodium hydroxide to form  $\text{NaHTe}$  or  $\text{Na}_2\text{Te}$ . Air or oxygen must be excluded, since oxidation will cause complete precipitation of tellurium. The  $+2$  valence is illustrated by tellurium monoxide ( $\text{TeO}$ ) and tellurium dichloride ( $\text{TeCl}_2$ ). The former is prepared by heating tellurium sulfite in vacuum at 200° C, the products being tellurium monoxide,  $\text{TeO}$ , and sulfur dioxide,  $\text{SO}_2$ . Tellurium dichloride is prepared by the direct union of chlorine and tellurium, an excess of chlorine yielding the tetrachloride,  $\text{TeCl}_4$  ( $+4$  valence). Similar iodides and bromides have been prepared. All are solids at 25° C. The tetrachloride and the tetrabromide melt at 214° and 380° and boil at 414° and 421° C, respectively. The chlorides or bromides react rapidly with water according to the following type of reaction:  $2\text{TeCl}_2 + 2\text{H}_2\text{O} = \text{TeO}_2 + 4\text{H}^+ + 4\text{Cl}^-$ . Although it is only slightly soluble in water, tellurous acid,  $\text{H}_2\text{TeO}_3$ , and its salts are known. Ionization constants reported for tellurous acid are:  $K_1 = 2 \times 10^{-8}$  and  $K_2 = 10^{-8}$ . Dissolved in strong acids,  $\text{TeO}_2$  forms the positive ion  $(\text{TeOOH})^+$ . The alkali tellurites are subject to air oxidation at elevated temperatures.

Tellurium dioxide can be prepared by heating the trioxide above its melting point but is most commonly prepared by the ignition or neutralization of tellurium basic nitrate,  $2\text{TeO}_2 \cdot \text{HNO}_3$ . The hexafluoride, telluric acid, and the tellurates illustrate the  $+6$  valence for tellurium. Contrasted with the other halides, the hexafluoride has a much lower melting and boiling point,  $-37.8^\circ$  and  $-38.9^\circ$  C, respectively, and a much higher heat of formation, 315,000 cal. Orthotelluric acid ( $\text{H}_6\text{TeO}_6$ ) is easily prepared by the chromic acid oxidation of tellurium basic nitrate or the hydrogen peroxide oxidation of an acid solution of tellurium dioxide. A solubility curve for telluric acid shows  $\text{H}_2\text{TeO}_4 \cdot 6\text{H}_2\text{O}$  to be the stable form below 10° C and  $\text{H}_2\text{TeO}_4 \cdot 2\text{H}_2\text{O}$  to be the form crystallized above 10° C. Salts of the hypothetical acids pyrotelluric,  $\text{H}_2\text{Te}_2\text{O}_7$ , and tetratelluric,  $\text{H}_2\text{Te}_4\text{O}_{13}$ , are known. Orthotelluric acid loses water upon heating. Conversion to tellurium trioxide,  $\text{TeO}_3$ , is complete at 300° to 360° C. The conversion to metatelluric acid,  $\text{H}_2\text{TeO}_4$ , is considered doubtful. If orthotelluric acid is heated in a closed tube at 140° C, a viscous liquid, allotelluric acid,

( $H_2TeO_4$ )<sub>n</sub>, where *n* is about 2.9, is formed. Presumably the transition point between orthotelluric and allotelluric acid is 131° C. Allotelluric acid is a relatively strong acid and exhibits properties quite different from those of the ortho acid. It is soluble in alcohol and separates sulfur from sodium thiosulfate. Upon standing, aqueous solutions hydrolyze and form orthotelluric acid,  $H_6TeO_6$ . Also reported are the acids  $H_6TeCl_6 \cdot 2H_2O$ , citron yellow, and  $H_6TeBr_6$ , red. Both tellurites and tellurates form coordination compounds, such as ammonium ditelluratehexamolybdate, potassium chromotellurate, and ammonium triarsenatotellurate.

Organic compounds vary in complexity from the relatively simple alkyl tellurides to the more complex cyclic compounds that contain tellurium in the ring. There are simple aliphatic compounds of the types,  $R_2TeX_2$ ,  $R_3TeX$ , and  $RTeX_3$ . Among the aromatic derivatives there are types  $R_2Te$ ,  $R_2Te_2$ ,  $RTeR'$ .

**Analytical.**—Like selenium, tellurium is easily precipitated from dilute hydrochloric acid solutions by reducing agents, such as sulfur dioxide or hydrazine hydrochloride. Two common reactions are used for the separation of tellurium from selenium. (1) Red selenium is precipitated from strong hydrochloric acid solutions by sulfur dioxide; tellurium is not. Upon separation of the selenium by filtration, the solution is diluted and the tellurium precipitated by further addition of sulfur dioxide. (2) The fusion of selenium and tellurium with potassium cyanide forms potassium selenocyanate,  $KCNSe$ , and potassium telluride,  $K_2Te$ . Bubbling air through a water solution of this mixture precipitates elemental tellurium. The addition of potassium iodide to a dilute acid solution of tellurium precipitates tellurium tetraiodide,  $TeI_4$ , which is soluble in an excess of potassium iodide, forming  $K_2TeI_6$ . Tellurium is commonly weighed as the element. Tellurous acid may be oxidized to tellurate by potassium permanganate. Tellurates are reduced quantitatively by titanous chloride.

**TELUGU**, one of the four literary languages of the Dravidian family, is spoken by about 35,000,000 people. It is the language of that part of Andhra Pradesh, India, beginning north of Madras city and extending northwest to Bellary, where Telugu meets Kanarese, and northeast to Orissa. It is an independent language of the family, with numerous peculiar features. Its literature dates from the 11th century, its inscriptions from the 7th. See **DRAVIDIAN**.

**TELUGU LITERATURE.** Telugu, like the other languages of south India, is of the Dravidian family (see further **TELUGU**; **DRAVIDIAN**).

**Early Period.**—The oldest extant examples of Telugu are in inscriptions of Cālūkyā kings, dating from the 9th century onward; the earliest literary work to survive is the 10th-century *Kumārāśambhavam* by Nannecoḍa, a lengthy poem based on a Puranic legend. Nannaya's version of the *Mahābhārata* (q.v.), written between A.D. 1022 and 1063, an abridgment of the Sanskrit epic, was completed by two later writers.

The well-known Indian literary form the *Śataka* ("century of verses") was particularly popular in Telugu; in the 12th century Vemana wrote a number of *Śatakas* on moral topics.

Two 15th-century poets should be mentioned: Śrīnātha (1365–440) and Potana (1400–75). The former wrote, among many other works, a version of the Nala and Damayanti story, an episode in the *Mahābhārata*, while the latter's masterpiece was the Telugu version of the *Bhāgavatapurāṇa*, which tells of the incarnations of the god Viṣṇu (see **VISHNUISM**).

**The 16th Century.**—The Vijayanagar Empire, whose court language was Telugu, was at its most powerful in the Deccan under Kṛṣṇadevarāya, who reigned from 1509 to 1530, and this period was the golden age of Telugu literature. The king himself was a poet and composed an epic, *Amuktamālyadā*, completed in 1520. It tells the story of a girl devotee of Viṣṇu, a foundling reared by a priest in the god's service, who had been the god's consort in a former birth. So much did she love Viṣṇu that she

used secretly to wear the garlands with which her adoptive father was later to adorn his image. When separated from him, she pined away, and he finally consented to her becoming his bride.

Two of the most famous poets at Kṛṣṇadevarāya's court were Peddanna and Timmanna. Peddanna wrote an epic called *Manucaritram*, and Timmanna one called *Pārijātāpaharaṇamu* ("Rape of the Night-Queen Flower"). This recounts an episode in the life of Kṛṣṇa (Krishna; q.v.), in which the god increases the jealousy between his two consorts, Rukmiṇī and Satyabhāmā, by presenting to Rukmiṇī a flower from the Night-Queen tree, which grows only in heaven, ruled by the god Indra. Satyabhāmā first upbraids and finally kicks her husband, who in the end agrees to uproot the tree to pacify her, a promise that involves a journey to heaven and a fight with Indra.

Another poet of about the same time is Suranna, who composed the *Kalāpūrnodayamu* in 1585. The story is of a comedy of errors: a heavenly maiden, Rambhā, and Nalakūbara, her lover, are tricked into falling in love with another pair of lovers, Kalābhūṣiṇī and Maṇikamdhara, who impersonate them. False and real lovers meet in a maze of errors, but the pretenders are eventually found out.

Tenālī Rāmakṛṣṇa is sometimes thought to have been jester to Kṛṣṇadevarāya, though this seems doubtful. Many stories have been attributed to him; of these, some describe his pranks (many at the expense of Tatācārī, a protagonist of Vaiṣṇavism), and some are in more serious vein.

**The 16th to the 19th Century.**—After the collapse of the Vijayanagar Empire in 1565, Telugu literature in the northern Deccan went through a period of stagnation and decadence. It flourished, however, at the courts farther south, where political conditions were more settled. Thanjavur (Tanjore) and Madurai attracted a number of Telugu writers between 1650 and 1830. Perhaps best known among these are the songwriters, especially Kṣetraraya, Tyāgarāja, and Śyāmā Śāstri. Tyāgarāja (1767–1847) was the greatest of the three. He wrote a number of songs in praise of Rāma (q.v.) in simple, direct Telugu, and these *Kīrtanas* ("songs of praise") are still sung. Such was the influence exerted by Tyāgarāja and others that Telugu came to be regarded as *par excellence* the language of music.

**Modern Period.**—The advent of the British brought Telugu into contact with Western literary forms and ideas, and some Europeans took an interest in Telugu. Chief among them was C. P. Brown, whose dictionaries, English-Telugu and Telugu-English, appeared in 1852.

The father of modern Telugu literature was K. Viresalingam Pantulu (1848–1919). He was quick to appreciate the possibilities of such Western forms as the novel and the drama. The first Telugu novel, *Rājasekharacaritramu*, was his adaptation of Oliver Goldsmith's *Vicar of Wakefield*. Under the influence of Rabindranath Tagore (q.v.), a new school of poetry attempted to convey direct personal experience, which would formerly have been considered in bad taste. The short story has been favourably received; Guruzada Appa Rao was the first short-story writer and Adivi Bapirazu a worthy successor.

**TELUKBETUNG**, a port in South Sumatra Province, Indonesia, capital of Lampung *Kabupaten* (residency), lies on the southern coast of Sumatra on Teluk (bay) Lampung, about 224 mi. SSE of Palembang by rail. Pop. (1961) 133,901. The immediate vicinity is mountainous, with Gunung (Mt.) Betung and Gunung Ratai to the west. The hinterland is low lying and was one of the earliest areas of transmigration from Java. The eruption of Krakatau (q.v.) in 1883 virtually destroyed the town. Between 1905, when immigration began, and the mid-1960s, the proportion of Javanese and Sudanese in the district rose to about one-third. Telukbetung is the chief port for the area, with services to Merak in Java.

**TEMA**, a port of Ghana, West Africa, formally opened in 1962, lies on the coast 18 mi. (29 km.) E of Accra, the capital.

Pop. (1960) 14,937. The choice of this site was due to its suitability for development into a deepwater harbour, enclosing 500 ac. (200 ha.), to serve the Volta Basin area and the eastern part of the country, Accra itself being unsuitable because of silting. The government acquired 64 sq.mi. (166 sq.km.) of land, north of the harbour and largely on the savanna, and entrusted its development to the Tema Development Corporation, established in 1952. The port now has three miles of breakwaters, ten deepwater berths, an oil tanker berth, a dockyard, warehouses, and transit sheds. A separate fishing harbour with cold-storage and marketing facilities is east of the lee breakwater. A "New Town" was planned to serve the harbour and provide industrial and residential facilities, the plan envisaging seven communities with a total potential population of 85,000 by 1970 and full modern amenities. Water supply, main drainage, and electricity are provided, and there are rail and road links with the country's main systems. About 800 ac. (325 ha.) were set aside for allocation to private industrial enterprise, and various industries have been established there, including chemical and aluminum works and an automobile assembly plant. (G. J. D. R.)

**TEMIR-TAU** (SAMARKANDSKI until 1945), a town in the Karagandinskaya (Karaganda) Oblast' of the Kazakh Soviet Socialist Republic, U.S.S.R., about 17 mi. (28 km.) N of Karaganda on the Samarkandski Reservoir (formed by the Nura River), is the terminus of a short branch railway from Solonichki Station on the Tselinograd-Karaganda line, a few miles east. Pop. (1959) 76,725. The town, which was once a small sawmilling settlement, developed rapidly during World War II with the establishment of a hydroelectric power plant and a steel mill. There are various technological institutes and a medical training school. There is also a synthetic rubber plant, and at Solonichki is the Karaganda metallurgical factory ("Kazakhstanskaya Magnitka"), completed in 1960. (G. E. W. R.)

**TEMNE** (TIMNE), a Negroid people occupying approximately 11,000 sq.mi. (4,450 ha.) in northwest Sierra Leone (q.v.). They number more than 500,000 and are divided by dialect into a northern and a southern group. Temne is a semi-Bantu language of the Niger-Congo family (see AFRICAN LANGUAGES). The Temne resemble the Mende (q.v.) in their pattern of settlement and live mainly by growing rice; women also fish. Rice, cattle, and goats are important for exchange and sacrifice. Land rights are based on descent from original settlers or conquerors, or on length of settlement. The Temne are divided into patrilineal, eponymously descended clans (*abuna*) that generally are not localized. The chief's office is partly religious, and he is sometimes a member of the Ragbenle and Poro secret societies. One or the other society conducts his installation ceremonies, during which he and some of his officials go into sacred seclusion. The women's Bundu society mainly prepares girls for marriage. Polygyny, levirate (qq.v.), and widow inheritance are practised; women attain some independence through trade and are sometimes influential in family affairs. Religion is concerned less with high gods than with prayers and sacrifices to nature and ancestral spirits. These beliefs are in decline through migration and industrialization, and the traditional activities of the secret societies are generally hidden except in more rural places.

**TEMPERA** is a kind of painting executed with paints that consist of pigment ground in a medium that is miscible with water; a few moments after application the paint is sufficiently resistant to water to allow overpainting with more colour. Thin, translucent layers of paint produce a clear, luminous effect and the colour tones of the successive brushstrokes blend optically. When the paint is skillfully built up, it will retain its luminosity, as well as the effect of its undercoats, as an opaque or semiopaque coating. Tempera is distinguished from the other aqueous paints which are either transparent (see WATER-COLOUR PAINTING) or solidly opaque (gouache, casein [qq.v.], poster colours). Tempera may

be applied in thin, transparent washes or in heavy, opaque touches when required, but these are not typical of the work as a whole.

Tempera paints have their distinctive properties because they are emulsions. An emulsion is a stable mixture of an oily ingredient (oils, fats, resins, waxes) and a thick, gummy or glue-like (colloidal) aqueous ingredient. The proverbial rule that oil and water do not mix does not apply when the oil is of an emulsifiable type and there is a good emulsifier in the water solution. The oily ingredient of an emulsion is dispersed in the aqueous solution in myriads of tiny round droplets. The binding ingredients in water colour, gouache and poster colours are not emulsions; they are simple gluey solutions.

The word tempera originally came from the verb "temper," i.e., to bring to a desired consistency; dry pigments were made usable by "tempering" them with a fluid binding and adhesive vehicle. The Italians distinguished such painting from fresco painting (q.v.), the colours for which contained no binder. The artist was said to "temper" his colours with egg or with oil. Eventually, after the rise of oil painting, the use of the word tempera became confined to its present meaning. In some circles, especially among artists who work solely for reproduction, "tempera" has been indiscriminately used to denote any opaque water medium and the labels on some aqueous colours in tubes and jars bear this name, but this usage is incorrect and confusing.

### TECHNIQUE

The standard tempera vehicle is a natural emulsion, egg yolk, thinned with water. The yolk of hen's eggs contains a fatty substance (egg oil) emulsified with a gummy substance (albumen) and a few minor ingredients, chief among which is lecithin, a powerful emulsifier and stabilizer. The man-made emulsions of more recent origin are variants of the original egg vehicle. Their purpose is to create some special property of manipulation or some effect for an individual requirement; they aim at duplicating or closely resembling the good properties of straight egg-yolk tempera, such as its tough, leathery permanent paint film.

In preparing the paint, the yolk is separated from the white and is dried by being rolled on a paper towel, and its sac is punctured; a pure yolk is thus obtained, without any white. The ingredients of pure egg yolk and their proportions govern the whole technique of egg tempera—its behaviour, its effects and its longevity. Egg white was never used in easel painting; it is a relatively weak and impermanent paint binder. The yellow colour of the yolk is imperceptible when pigmented; moreover, it is a fugitive colouring matter (carotene) which soon disappears on exposure. The pigments (the same as those used in water colour) are ground to paste consistency with water and kept in screw cap jars. Prior to each day's work the artist mixes with egg yolk as much of a colour as he needs. He paints with fine red sable water-colour brushes; a skilled technique of brushwork is gained from experience. The three basic points of control are the amount of water used, the loading of the brush and the manner of stroking. It is a deliberate, controlled method, adaptable to carefully planned work rather than to spontaneous painting. A finished drawing (cartoon), in which all the artist's creative problems are worked out, is made first; this is traced on the ground. The artist's efforts can then be devoted to the technique and the development of colour and painterly effects. The special ground for tempera painting is a rigid wood or wallboard panel coated with gesso, which is a brilliant white, ivory smooth, fully absorbent preparation made of precipitated chalk and rabbitskin glue.

Variants of the pure egg-yolk vehicle have been developed to widen its use among contemporary artists, although earlier painters chose to develop a superlative skill in the handling of a somewhat difficult and intractable material rather than to make the material itself amenable to a more easily acquired skill. Among the man-made emulsions a popular one is prepared by shaking or homogenizing whole egg with linseed oil; this vehicle is preferred by many painters to that of pure yolk. Another is gum tempera, the standard recipe for which contains gum arabic or cherry gum emulsified with a blend of dammar varnish and stand oil. This vehicle is also well-liked by numerous painters; it can produce an

Madonna and Child" Giotto (Giotto di Bondone)

"The Presentation in the Temple" by an unknown 15th-century Byzantine painter. 17½ × 16½ in. (44½ × 42¼ cm.)

## EARLY DEVELOPMENTS IN TEMPERA PAINTING

The earliest European tempera paintings were done by Byzantine artists (above) who followed circumscribed traditions using primitive methods. Duccio (left), and other 13th-century Italian artists, developed a standard, controlled egg tempera technique for painting on wood panels. Slightly later pre-Renaissance painters, such as Giotto (top left), produced tempera works which hint at the technical brilliance and artistic sophistication that were to come

"The Calling of the Apostles Peter and Andrew" by Duccio (Duccio di Buoninsegna)

"The Crucifixion" by Carlo Crivelli, c. 1490.  $29\frac{5}{8} \times 21\frac{3}{4}$  in. ( $75\frac{1}{4} \times 55\frac{1}{4}$  cm.)

"An Apostle" (St. John or St. Peter) by Piero della Francesca

#### LATER DEVELOPMENTS IN TEMPERA PAINTING

The works of the 15th-century Italian artist Carlo Crivelli (top left) and his contemporary Sandro Botticelli represent the highest possible degree of skill and refinement using pure egg tempera. Since tempera is a meticulous medium, best suited to a deliberate and largely linear style, only the addition of oil could produce tempera works of greater flexibility and flow. Thus, all the paintings on Plates II and III, except the Crivelli "Crucifixion," though primarily tempera, probably employ some oil, either in the form of infinitely refined glazes (as in the painting at left and those at the bottom of Plate III) or mixed in some way with the aqueous tempera itself (as in the painting above and at the top of Plate III). With the demand for more spontaneous and brightly coloured works and the development of oil painting to meet it, tempera became a neglected medium, important only to art historians. In the 20th century such artists as Ben Shahn and Andrew Wyeth (Plate IV) have helped to revive interest in it

"Portrait of a Doge" by Gentile Bellini.  $21\frac{1}{2} \times 17$  in. ( $54\frac{3}{8} \times 43\frac{1}{8}$  cm.)

"St. Francis in Ecstasy" by Giovanni Bellini. 48½ × 55 in. (123¼ × 139¾ cm.)

"Portrait of a Donor" by Hans Memling, c. 1485. 13¾ × 10¾ in. (34¾ × 25¾ cm.)

"Jean de Gros" by Rogier van der Weyden, 1450-60. 15¾ × 11¼ in. (38¾ × 28¾ cm.)

"Mine Disaster" by Ben Shahn, 1948. 24 × 30 in. (60 3/4 × 76 1/4 cm.)

"Christina's World" by Andrew Wyeth, 1948. 32 1/4 × 47 3/4 in. (81 9/16 × 121 1/4 cm.)

almost impasto effect when desired. Wax temperas are made from a group of experimental recipes and have the reputation of producing delicate, sensitive effects. Casein colours are opaque water paints, not correctly classified as tempera. Modern tempera paintings are sometimes varnished or overpainted with thin, transparent oil glazes to produce full, deep-toned results, or they are left unglazed for blond effects. Unvarnished tempera paintings, especially the pure egg-yolk variety, will assume a pleasing, satiny sheen when polished with cotton wool.

### CASEIN PAINTING

For more robust, solid or spontaneous effects than are obtainable with tempera, artists have used colours ground in a solution of casein (*q.v.*). In the form of homemade curd made from soured skim milk, it has been a traditional adhesive and binder for more than eight centuries. Refined, pure, powdered casein which can be dissolved with ammonia has been used by artists for easel and mural paintings since the latter 19th and early 20th centuries. More recently, ready-made casein paints in tubes have come into very wide use to create effects that approach those of oil paintings. Casein painting permits the use of bristle brushes and a moderate impasto, like oil painting, but not the fusion of tones. It is preferred by some because of speedy drying and mat effects. When dry, the paint becomes water-resistant to a considerable degree. Casein paintings may be varnished to further resemble oil paintings, and they are frequently glazed or overpainted with oil colours. Proper technique calls for the use of rigid boards or panels; casein is too brittle for canvas.

### HISTORY

No positive date is assigned to the first use of egg yolk as a binder of colours; it is so readily available that it may have served the most primitive cultures. The earliest European forerunners of a controlled egg-tempera medium are found among the religious paintings of the Byzantine era. By the 13th century a well-developed, standard technique on wood panels emerged in Italy; the works of Duccio (*c.* 1255–1319) in Siena and Cimabue (*c.* 1240–*c.* 1302) in Florence are outstanding examples. The medium served well when panel painting moved to a higher plane of artistic and technical sophistication as in the tempera paintings of Giotto (1267?–1337) and the Lorenzettis of 14th century Siena. Anonymity and routine following of symbolism gave way to a more individual, personal or inventive manner; the madonnas and saints were depicted as actual people. The Italian schools thereafter developed until their style of painting culminated in a refinement and perfection which it is not possible to excel with pure egg tempera. A number of painters exhibit this high stage of development; examples are the Venetian Carlo Crivelli (*c.* 1430/35–*c.* 1493/95) and, perhaps the most accomplished of all, the Florentine Sandro Botticelli (1444/5–1510). With the changing demands of the times, art forms evolved from the generally dry and deliberate linear styles that were admirably served by tempera, to a more flowing, intensely coloured, spontaneous and juicier kind of painting, with smooth blending of colours and tones. Artists necessarily turned to the use of oily materials. (*See OIL PAINTING, TECHNIQUE OF.*)

The earliest examples usually cited in historical accounts of oil painting are actually tempera paintings with thin, transparent oil glazes; such pictures are perhaps more accurately classified as tempera painting in its ultimate form. But before oil painting supplanted it, tempera was used for a group of paintings that constituted a transitional stage; the medium was still aqueous tempera, but with properties that could scarcely have been duplicated by strict adherence to the pure egg-yolk technique as used from Giotto to Botticelli. In the paintings of this transitional group there was fusion of tones and a choice of scenes and subjects that challenged the potential of egg yolk and presaged oil-painting technique. Perhaps a little oily ingredient was incorporated into the paint in some manner; it seems to require some such alteration to duplicate the effects of Carpaccio (*c.* 1460–1525/26) for instance, or of Giovanni Bellini (*c.* 1430–1516), who eventually did employ oil paint. Use of old techniques continued long after the

introduction of new ones, so the rapidly changing practices of the 15th century cannot be attributed to specific dates.

In the following centuries tempera was practised sporadically; it never became a totally defunct technique. In the mid-19th century its literature was studied intensively, although academically for the most part, for its relationship to oil painting. Egg tempera is completely and satisfactorily documented and the technique can be easily reconstructed from writings and from hundreds of examples that have survived in fine condition. One prominent source of information is *The Book of the Arts or Treatise on Painting*, written in the late 14th or early 15th century by Cennino Cennini; it is a complete treatise on artists' techniques of the Gothic and early Renaissance periods. Cennini's idol was Giotto, and the book stems directly from Giotto's studio. Besides tempera it covers fresco, oil paints for decorative work and a number of studio practices. It also contains observations on painting, the proper personal behaviour and decorum of artists, the minutiae of artists' materials and procedures (*e.g.*, "the yolk of a town hen's egg is paler than those of country hens").

Artists in Europe and the United States in the latter part of the 19th and the early part of the 20th centuries found both pure and oil-glazed tempera techniques, such as those used by the early Italian and Flemish masters, very appropriate for their own work, particularly for blond effects. A strong revival of tempera followed, elevating it to a significant position among standard 20th-century techniques.

**TEMPERAMENT**, in psychology, refers to that aspect of personality concerned with emotional dispositions and reactions, and their speed and intensity; the term often is used to refer to the prevailing mood of a person. Historically, the notion of temperament in this sense originated with Galen (*q.v.*), who developed it from an earlier physiological theory based on the assumption of four basic body fluids (humours): blood, phlegm, black bile, and yellow bile. According to their relative predominance in the individual, they were supposed to produce, respectively, a sanguine, phlegmatic, melancholic, or choleric temperament (Lat. *temperare*, "to combine or mingle in due proportion"). This theory constitutes the first of many attempts to group human beings into types, and its stress on the physiological determination of temperament is echoed in modern theories emphasizing the action of the endocrine glands; *e.g.*, an increase in the secretion of adrenaline produces heightened emotional reactivity (*see* EMOTION). Modern psychology attributes primary importance to the activity of the autonomic nervous system (*see* NERVOUS SYSTEM), and particularly its sympathetic branch, in accounting for emotional reactivity; autonomic over-responsiveness is intimately linked with neurotic dispositions, but such responses can easily be conditioned (*see* CONDITIONING), and consequently individual differences in ease of conditioning (also probably innate) likewise play their part in determining temperament.

External physical characteristics have often been supposed to permit positive identification of different temperaments, but empirical studies have almost universally yielded relatively low correlations. Very thin, lean people tend to be introverted and to develop symptoms of anxiety and depression when suffering from neurotic disorders; very broad, fat people tend to be extroverted and to develop symptoms of hysteria and psychopathy when suffering from neurotic disorders. But these relationships are slight and of little help in prognosis or treatment.

Modern investigations have left little of Galen's original theory standing and involve such methods as the experimental measurement of a person's emotional reactions in standardized stressful situations and detailed statistical analysis of the relationships observed. The resulting picture is highly complex, revealing, among other things, a tendency for individuals to respond con-

sistently to stress with only one of the many parts of the body controlled by the autonomic system, and it is this part that is most vulnerable in neurotic breakdown. See also PERSONALITY; HYSTERIA.

**TEMPERAMENT, MUSICAL**, a term applied principally to systems for tuning instruments of fixed pitch, such as the keyboard instruments. These systems were designed to produce, by means of tempering (*i.e.*, a slight mistuning), a maximum number of intervals (especially major thirds) both melodically and harmonically acceptable to the ear.

**Just Intonation**.—When two notes are sounded together, they are pleasing to the ear when their wavelengths or frequencies bear a simple numerical ratio to each other (or very nearly so). Unisons have a frequency ratio of 1:1 and octaves 2:1. These intervals are so fundamental that they are accepted in all systems and need not be tempered. The next most harmonious interval is the perfect fifth, with the ratio 3:2 (its complement being the perfect fourth, with the ratio 4:3).

To add intervals together, the frequency ratios have to be multiplied together. Now, if fifths are added together, a new note is formed each time. For instance, in just intonation (*i.e.*, in mathematically exact intervals), starting with C and G, one then obtains D such that D and C have the ratio 9:4 or, bringing the D down an octave, the ratio 9:8. This interval is a major tone and is still reasonably concordant. If the process is repeated, one obtains an E giving with C an interval of two major tones with the ratio of 81:64, which is unbearably discordant. This may explain why in early medieval music, dominated by the theory of the pure fifth, the tone, fourth, fifth and seventh were regarded as concordant but the major third as discordant. If, however, a natural major third is sung, the frequency ratio will be 5:4, *i.e.*, 80:64.

The difference between the pure major third and the one obtained from four pure fifths is an interval with the ratio of 81:80 and is known as the comma of Didymus. The reason for this is that just as  $3 \times 3 \times 3 \times 3 = 81$  is a different number from  $5 \times 16 = 80$ , so the two E's are actually different notes. The problem lies in the fact that musical notation recognizes only one E and musicians similarly want only one E. The question then arises as to what extent this duplication applies to other notes or to, say, a whole major scale.

At this stage it becomes difficult to visualize ratios of large numbers and an additive numerical measure for intervals becomes necessary. This is easily obtained by taking logarithms of the frequency ratios; by convention, the octave is divided into 1,200 cents. Thus:

$$\text{No. of cents} = \frac{1,200}{\log 2} \times \log \text{ of frequency ratio}$$

The ratios and cents of the two independent basic intervals are: perfect fifth = 3:2, 701.955; and major third = 5:4, 386.314. As all musical intervals are derived from ratios of products of the prime numbers 2, 3 and 5 only, cents of all the other intervals can be obtained by addition and subtraction of these two intervals. (Trumpets and horns produce "harmonics" that include other notes based on the numbers 7, 11, 13 and 17, but the player is expected to modify these in performance.) Thus the following intervals are obtained: perfect fourth (4:3,  $1,200 - 701.955 = 498.045$ ); major tone (9:8,  $701.955 - 498.045 = 203.910$ ); diatonic semitone or minor second (16:15,  $498.045 - 386.314 = 111.731$ ); minor sixth (8:5,  $1,200 - 386.314 = 813.686$ ); minor third (6:5,  $701.955 - 386.314 = 315.641$ ); major sixth (5:3,  $498.045 + 386.314 = 884.359$ ); chromatic semitone or augmented unison (25:24,  $386.314 - 315.641 = 70.673$ ); and the difference between a diatonic semitone and a chromatic semitone = 41.058 cents. Also, the comma of Didymus =  $4 \times 701.955 - 2 \times 1,200 - 386.314 = 21.506$ . This interval is consequently more than one-fifth of an equal-tempered semitone.

In the C major scale the relative frequencies and cents to the nearest whole number from the first note are: C (24, 0); D (27, 204); E (30, 386); F (32, 498); G (36, 702); A (40, 884); B (45, 1,088); C (48, 1,200). All the possible intervals in the octave

can be checked by subtracting the cents. They all come out right except D - A = 680 is not a fifth and D - F = 294 is not a minor third. As they are both too narrow by 22 cents (the comma of Didymus), the solution might appear to be to alter D to 182 cents. This makes D - A and D - F right but then D - G and D - B would be too wide by a comma. Further, the note B<sub>b</sub> would have to be 996 to be a fourth above F or 1,018 to be a minor third above G, again differing by a comma.

If adjacent notes in the scale are subtracted the result is the following intervals: 204, 182, 112, 204, 182, 204, 112. In other words, an octave consists of two diatonic semitones of 112 cents, three major tones of 204 cents and two minor tones of 182.404 cents (ratio 10:9). As music recognizes only one type of tone, one requirement for a practical scale is to standardize on some compromise size of tone.

**Tempered Scales**.—*Mean Tone Temperament*.—It has been shown that if the fifths are kept pure by making all tones of 204 cents, the major thirds are unbearably sharp by a whole comma. If all the tones are minor, neither fifths nor thirds are right. If, however, one takes an average, or mean tone, of 193.157 cents, the major thirds will be pure and the fifths will be only a quarter of a comma flat. The semitones will have to be equal to half the difference between the octave and five mean tones, or  $(1,200 - 5 \times 193.157) \div 2 = 117.107$ ; *i.e.*, one-quarter comma sharp. The chromatic semitone will then be tempered to  $193.157 - 117.107 = 76.050$ , also a quarter comma sharp. The fifth will be  $3 \times 193.157 + 117.107 = 696.578$ . In the mean-tone system the difference between a minor second and an augmented unison, *e.g.*, C $\sharp$  to D $\flat$ , is still 41 cents, or just over two-fifths of an equal-tempered semitone. Consequently, on keyboard instruments, if there are only five accidental keys within the octave it is necessary to decide which are the most useful five. The usual choice is C $\sharp$ , E $\flat$ , F $\sharp$ , G $\sharp$  and B $\flat$ . If an A $\flat$  is needed (*e.g.*, to use with E $\flat$ ) and G $\sharp$  is used instead, the interval is  $772.628 - 310.264 = 462.364$ , which is 35.681 cents out for a pure fourth and produces a howling sound known as the "wolf."

*Equal Temperaments*.—There is a second criterion for tempering a practical scale: fretted instruments, such as guitars, lutes and viols, that have strings tuned to any interval other than unisons or octaves need a cyclic division of the octave so that pure octaves can be obtained from all appropriate combinations of two strings and two frets. The only way to do this is to divide the octave into a certain number of exactly equal intervals. As a scale consists of five tones and two semitones, the octave must be divided into  $5x + 2y$  parts where  $x:y$  is approximately 193:112, or 1.7:1.

(1) The 12-note system. The simplest case is when  $x = 2$  and  $y = 1$ . The octave is then divided exactly into 12 and this gives the normal equal temperament. All semitones and minor seconds are tempered to 100 cents each and the tone becomes 200 cents, etc. The same note has to serve both for C $\sharp$  and for D $\flat$  (although music does require two different notes) and F has to be used for E $\sharp$ , and so on. The major third is 14 cents too sharp and is just on the limit of pleasantness. The overriding merit of this system is its simplicity.

(2) The 19- and 31-note systems. If  $x = 3$  and  $y = 2$ , the octave is divided into 19 equal intervals of 63 cents. The notes are in the order: C, C $\sharp$ , D $\flat$ , D, etc., with a note between E and F for both E $\sharp$  and F $\flat$ . If  $x = 5$  and  $y = 3$ , the octave is divided into 31 equal intervals of 38.7 cents. The order of notes is then C, D $\flat$ , C $\sharp$ , D $\flat$ , C $\sharp$ , D, . . . E, F $\flat$ , E $\sharp$ , F, . . . This system is remarkably close to mean-tone tuning (and to just intonation) as can be seen in the table of comparisons below. A harpsichord built in 1606 by Vito Trasuntino has 31 keys to the octave; it could be tuned exactly according to this system.

	Just	Mean Tone	12-note system	19-note system	31-note system
Chromatic semitone . .	71	76	100	63	77
Diatonic semitone . .	112	117	100	126	116
Tone . . . . .	182 or 204	193	200	190	194
Minor third . . . . .	316	310	300	316	310
Major third . . . . .	386	386	400	379	387
Fifth . . . . .	702	697	700	695	697

**History.**—During the late medieval and Renaissance periods the 12-note equal temperament must have been familiar, as is shown by (1) the extensive use of fretted instruments such as the lute and viol; (2) organists' instructions to tune by fifths, tempering them just sufficiently to make the thirds usable; and (3) a few keyboard and viol fantasias that modulate enharmonically through all the possible keys. The equal-tempered major third, especially on keyboard instruments, is, however, offensively sharp to sensitive ears and toward the end of the Renaissance theorists were experimenting with other systems of tuning that produced better thirds.

The baroque era brought the decline of the lute and viol and the rise of wind instruments whose fingering favoured purer thirds, and this encouraged the introduction of mean-tone tuning. This system, however, allows little modulation and no enharmonic modulation.

Accordingly, as the technique of composition developed in the 18th century, despite attempts at duplication of accidentals on organs, the change to equal temperament was advocated by J. S. Bach and others. It should be remembered that an infinite range of intermediate tunings between mean tone and equal temperament is possible; such intermediate tunings were probably much used in earlier centuries. (G. F. OL.)

**TEMPERANCE.** The word temperance, which strictly means moderation, acquired a particular meaning in connection with intoxicating liquor and is here used in that sense.

**History.**—Ever since man in some distant age first discovered the process of fermentation by which sugar is converted into alcohol and carbonic acid, and experienced the intoxicating effects of the liquor so produced, there has been a temperance problem. The records of the ancient oriental civilization contain many references to it and from very remote times efforts were made by priests, sages and lawgivers in India, Persia, China, Palestine, Egypt, Greece and Carthage to combat the injury of drunkenness to the individual and society. But the evil appears never to have been so great or the object of so much attention in the ancient world as it came to be in western countries, especially in modern times. (See ALCOHOLISM.)

The intoxicating drinks consumed by ancients were wines obtained from grapes or other fruits and beers made from various kinds of grain. These products were not confined to the east, but were also known to the ancient civilizations of Mexico and Peru and to other peoples who used the sugar-containing juices and other substances indigenous to their countries. In the time of the Romans the people of northern Europe used fermented liquors made from honey (mead), barley (beer) and apples (cider) in place of grape wine. All such drinks produce intoxication if taken in sufficient quantity, but their action is much slower and less violent than that of distilled spirits. This difference is a result of the greater concentration of alcohol in distilled spirits, which leads to a more rapid absorption of the alcohol into the blood stream and to a higher concentration of alcohol in the blood.

Potable distilled spirits were apparently not known until the 13th century. The distilled essence of wine or aqua vitae (brandy) is mentioned then as a new discovery by Arnaldus de Villa Nova, a chemist and physician, who regarded it, from the chemical or medical point of view, as a divine product. It probably came into use gradually, but once the art of distillation (*q.v.*) had been mastered it extended to other alcoholic products in countries where wine was not produced. (See also ALCOHOLIC BEVERAGES, DISTILLED.)

The concentrated form of alcohol thus evolved long carried with it the prestige of a divine essence given to it in the middle ages. It had potent properties and was held to possess great virtue, a view embodied in the name "water of life," and at one time almost universally held. Ardent spirits seemed particularly desirable to the people of the cold and damp regions of northern Europe, where people took to it with avidity when it became cheap and easily accessible. That happened in England in the early part of the 18th century, and from the ensuing bad results there eventually arose the modern temperance movement. The legislature had been busy with the liquor traffic for more than two centuries

previously, but its task had been the repression of disorder: drunkenness was a nuisance and had to be checked in the interests of public order. It is significant that though drunkenness had been prevalent from the earliest times, necessity for attempts at legislative control did not arise until after the introduction of distilled spirits.

Intemperance was one of many problems which arose during the latter half of the 18th century to become the subject matter of social reform in the 19th century. A breach had been made in the unthinking traditional belief in the virtue of alcoholic liquor, and medical thought, as soon as it began to be concerned with health as distinguished from the treatment of disease, took up the matter. In 1804 Thomas Trotter of Edinburgh, Scot., published a book on the subject, an expansion of his academic thesis written in 1788. Benjamin Rush of Philadelphia, who had studied in Edinburgh and London, wrote a striking paper on the subject in the same year; and soon after this the organized temperance movement got under way in the United States.

**Temperance and Prohibition Organizations.**—In 1808 a temperance society was founded at Saratoga, N.Y., and in 1813 the Massachusetts Society for the Suppression of Intemperance made its appearance. These seem to have been the earliest organizations, though the device of a pledge of abstinence had been introduced in 1800. The movement made rapid progress, mainly under the influence of the churches. In 1826 the American Society for the Promotion of Temperance was founded in Boston, Mass., and by 1833 there were 6,000 local societies in several states with more than 1,000,000 members. The campaign was directed primarily against the use of distilled spirits only, and the proposal to include all alcoholic drinks in the pledge of total abstinence, though adopted by a few societies, was rejected in 1833 by the American society, but accepted in 1836 and retained thereafter.

In Europe the earliest organizations were formed in Ireland. A temperance club is said to have been started at Skibbereen in 1818, and others followed; but it was in 1829 that the organized movement began to make effective progress with the formation of the Ulster Temperance society. By the end of that year there were 25 societies in Ireland and 2 or 3 in Scotland. In 1830 the movement spread to Yorkshire and Lancashire, and supported a newspaper called the *Temperance Societies' Record*, according to which there were then 127 societies with 23,000 paying members and 60,000 associated abstainers. In 1831 the British and Foreign Temperance society was founded in London with the bishop of London (Charles Blomfield) for president and Archbishop John Sumner for one of the vice-presidents. This important society, of which Queen Victoria became patron on her accession in 1837, came to an end in 1850, when the cause was under an eclipse.

The most remarkable episode in the temperance campaign at this period was the mission of the Rev. Theobald Mathew of Cork, commonly known as Father Mathew, greatest of all temperance missionaries. He traveled through Ireland in the years 1838-42 and everywhere excited intense enthusiasm. People flocked to hear him and took the pledge in crowds. In 1841 the number of abstainers in Ireland was estimated to be 4,647,000; in three years the consumption of spirits fell from 10,815,000 to 5,290,000 gal. This was not all due to Father Mathew, because great depression and distress prevailed at the same time, but he exercised an extraordinary influence. In 1843 he went to England, where he had less (though still great) success, and in 1850 to America. He died in 1856, by which time the cause had fallen into a depressed state in both countries. In the United States a flash of enthusiasm of a similar but smaller character, known as the Washingtonian movement, had appeared. In 1845 a law prohibiting the public sale of liquor was passed in New York state but repealed in 1847; in 1851 Maine adopted prohibition.

The Church of England Temperance society, much the largest at mid-20th century, was founded in 1862 and reconstituted in 1873. It was incorporated in 1907, reconstituted again in 1911 and 1921, and recognized by the church assembly in 1923. It carries on an extensive publication department and educational courses, police court and prison gate missions to seamen, traveling vans and inebriate homes.

The United Kingdom alliance founded in 1853 became the chief political organization. Its object was prohibition of the drink trade, but it adopted the policy of *gradual prohibition* by means of local option. It began publication of the "national drink bill," a calculation of the national expenditure on alcoholic liquors. Other legislative organizations in Britain are the National Temperance League, the British Temperance League, the National United Temperance Council, the National Temperance Federation, the Temperance Legislation League and others in Scotland, Ireland and Wales. There is also a Royal Army Temperance association and a Royal Navy Temperance society. International societies enumerated are the World League Against Alcoholism, the World Prohibitive Federation, the International Orders of Good Templars and the World's Woman's Christian Temperance union.

This temperance and total abstinence became the objects of the united efforts of education and legislation in many regions. This union was probably promoted in part by the fact that once a person has become an alcoholic recovery usually requires total abstinence. In later years the organized movement in many countries embraced both voluntary and compulsory abstinence and combined the inculcation of individual abstinence with the promotion of legislation for the reduction or suppression of the alcoholic liquor traffic. On the whole the latter predominated, particularly in the United States, where organized agitation made temperance or prohibition partly a political question and produced various experiments in legislation. (See **PROHIBITION**.) Besides combining the moral and the political elements the modern movements were characterized by the following features: (1) international organization; (2) organized co-operation of women; (3) juvenile temperance; (4) teaching of temperance in schools and elsewhere; (5) scientific study of alcohol and inebriety.

**International Organization.**—The first international temperance organization appears to have been the Order of Good Templars, formed in 1851 at Utica, N.Y. It spread over the United States and Canada, and in 1853 was introduced into Great Britain. Several years later it was extended to Scandinavia, where it became very strong. Temperance societies had previously existed in Norway from 1836 and in Sweden from 1837; these seem to be the earliest examples on the continent of Europe. The Good Templars organization also spread to several other European countries, to Australasia, India, south and west Africa and South America. Several other international societies were founded, and international congresses were held, the first in 1880 at Antwerp, Belg. A World's Prohibition conference was held in London in 1890, attended by about 100 delegates from temperance societies in nearly all parts of the world. This conference resulted in the foundation of an International Prohibition Federation embracing every country in Europe with three or four minor exceptions, the United States, Mexico, Argentina, much of the British commonwealth, China, Japan, Israel, Tunisia and Hawaii.

**Templars Anonymous.**—This is an organization of former alcoholics who have become total abstainers. It is a national organization, started in the United States but gradually extended to other countries. Its primary object is to aid by education and personal service other alcoholics to recover from their addiction.

**W.C.T.U.**—The organization of women who became international dates from 1849, when the National Woman's Christian Temperance union was founded at Cleveland, O. It employs clubs and societies as well as joint efforts in promoting legislation. About 1880 Frances Willard, who had been the moving spirit of the union, carried this organization to various other lands and formed the World's Woman's Christian Temperance union, which is the largest and best known of the kind in existence.

**Juvenile Groups.**—The teaching of children in temperance organization goes back to 1847, when a society of juvenile abstainers who had taken the pledge was formed at Leeds. It took the name of Band of Hope. The practice spread, and in 1849 a Band of Hope union was formed. Within the next century a number of such unions were established in Scotland, Ireland and separate unions in England; the Bands of Hope were said to number about 1,000 in all.

**School Programs.**—The teaching of temperance in the feature of social education and moral preparation was a private effort in 1852 when John Hope inaugurated a weekly visitation of day schools in Edinburgh. In 1853, at the invitation of the National Temperance League, St. John Richardson wrote his *Temperance Lesson Book*, which was adopted by many schools as a primer. In 1856 when traveling lecturers was taken up by the U.K. Band of Hope and the example was followed by many other societies who spent large sums on itinerant lecturers. The Church of England temperance society carried on similar work. In 1904 the education in Ireland made hygiene and temperance a subject in the public schools. In 1907 the English board of education issued a syllabus of temperance teaching. In Scotland hygiene and temperance were adopted by many local educational authorities.

The question of temperance teaching in the United States was first taken up by the Woman's Christian Temperance union in 1879; it was believed that by teaching the physiological effects of alcohol to all children the problem of intemperance would be effectually solved, and a systematic political campaign was planned and carried out for the purpose of obtaining compulsory legislation to give effect to this idea. The campaign was successful in New York in 1884, in Pennsylvania in 1885 and subsequently in other states. Laws were passed in every state making antialcohol teaching part of the curriculum in the public schools. Teaching of temperance became compulsory in Canada except in Quebec and Prince Edward Island; in France in 1902; in Sweden in 1904; and in Ireland. It became optional in Australia, South Africa, some parts of India, Belgium, Finland, Denmark, Norway, Germany and Switzerland. See also **LOCAL OPTION**; **LIQUOR LAW**.

**TEMPLARS.** The Knights Templars or Poor Knights of Christ and of the Temple of Solomon was one of the three great orders of knighthood founded at the time of the Crusades (see **KNIGHTHOOD, CHIVALRY AND ORDERS**). It was founded in the early years of the Kingdom of Jerusalem (see **CRUSADES**) when the crusaders controlled only a few towns. The first headquarters of the order were open to all knights, and the order was known as the Order of the Temple of Solomon. The order was founded by Hugues de Payens, a knight of the French king, who came to the Holy Land to devote his life to the service of God and to the patriarch of Jerusalem and took vows of poverty and obedience to the rule of the Augustinians. The king of Jerusalem gave them quarters in a wing of the palace, next to the al-Aqsa Mosque in the area of the former Jewish Temple; and from this circumstance they derived the name.

Their numbers increased rapidly: many knights who had gone on crusade or pilgrimage, even those with considerable possessions, joined the order. Hugues de Payens, who was the first master, died in 1120, and was succeeded by Bernard of Clairvaux. At the Council of Troyes (1128) the rules and of the Templars were carefully studied and were found to be in need of further precepts, derived from the Benedictine rule and drawn up by St. Bernard of Clairvaux. The order had become very powerful. A letter from Hugues de Payens to the king of Jerusalem, dated 1120, mentioned that many of the knights were leaving up were reported to have been killed in the Holy Land. This probably explains why St. Bernard (whose uncle André de Montbard was afterward became grand master) to write a treatise of the order's aims. In his treatise *De laude novae milicie* St. Bernard emphasized the importance of the order, contrasting the pure and disinterested life of the

with the dissolute behaviour of those who remained in the order. He called especially on those excommunicated for heresy and who had undertaken a pilgrimage to the Holy Land in order to obtain absolution, to ensure a real amendment by joining the order.

Raynbro de Payns died in 1136. His successor as grand master, Bernard de Chalon, obtained from Pope Innocent II confirmation of the order's rule and customs and was granted certain important privileges. By Innocent's bull (*Omne datum optimum*, 1139) the Templars were exempted from paying tithes and were allowed to have their own chapels, served by priests of their own order. The order was also exempted from the jurisdiction of any secular authority whose diocese it might have property. This privilege, which was the whole character of the order; released from obedience to any secular authority of Jerusalem, it was able to diversify its activities and to become much more than a confraternity of knights of the Holy Sepulchre.

**Rule and Customs of the Templars.**—The *regula promulgatum Christi* was drawn up in Latin at the time of Bernard de Chalon and revised (c. 1130) by the patriarch of Jerusalem. A French version, expanded to include various details (the *retraites et établissements*) made by successive grand masters of the order, was made c. 1188. When the Teutonic Order was established as a military order in 1198, their rule was based on that of the Templars.

The Templars were divided into four classes: knights, sergeants, and servants. Only the knights who were of noble birth wore the distinctive white surcoat adopted in 1130 and after 1148 with a red cross. The order was controlled by the grand master, but he could make no important decisions without the assent of the general chapter. For the election of a grand master the chapter met in special session. It first chose 12 knights; these 12 co-opted 2 others, the 4 another 2, and so on until 12 had been formed. Of these, 8 were knights, 4 sergeants. The 12 men chose one of the chaplains to act as their spokesman (he was supposed to represent Christ amidst his apostles); these 13 elected a new grand master. Each house (Temple) of the order was ruled by a commander, who, like all the knights, owed obedience to the grand master. If the Templars had more than one establishment in a particular country, the commanders there were subordinated to a grand commander (called the visitor or preceptor).

The fighting force consisted of the knights and the sergeants (being of non-noble birth). All were bound to accept the vows of poverty, chastity, and obedience. Their equipment, although modest, was never to be rich, and the personal arms to which each individual Templar was vowed was indicated by his seal, which portrayed two knights mounted upon horses. Besides the knights who took perpetual vows, the order also received temporary members, whose vows covered only the period of their service.

**Activity of the Templars in the Levant.**—After the fall of Jerusalem in 1187, the Templars continued their activities. They continued to desert pagans and to convert Jews. The establishment of the Latin States made the Holy Land become much safer. Meanwhile a steady flow of knights and sergeants came to the Holy Land in order to join the Templars. They also acquired considerable property. Thus the Knights became a vital element in the defense of the Latin States, extending over a large area of the Holy Land. They were the only knights to fight for the king of Jerusalem or the other of the Latin principalities in any way against the Muslims.

The Templars possessed no real fortresses of their own, but they came to build many castles in Spain, where they were active in the Reconquest. But from the mid-12th century onwards the Hospitallers (see SAINT JOHN OF JERUSALEM) and the Templars were in receiving grants of pasture and land in the Latin States. When in 1187 King Baldwin III of Jerusalem was forced to flee the Holy Land, he entrusted its defense to the Templars who alone

had sufficient knights adequately to garrison it. At about the same time they were also given custody of Safita (Chastel-Blanc) and Tortosa in the county of Tripoli, and Baghras and other fortresses in the principality of Antioch. In these castles and the lands depending on them, the Templars very soon became completely independent of the king or any other territorial ruler.

Furthermore, the order soon acquired such weight that the grand masters agreed to treat on equal terms with temporal sovereigns. At the siege of Acre (1187), when a breach had been made in the town walls, the grand master Bernard de Tremelay (who was subsequently killed in the action) presumed to restrict to the Templars the honour of fighting their way in. When King Amalric I sought to punish (c. 1173) a Templar, Walter de Mesnil, who had ambushed Assassin envoys traveling under the king's safe conduct, the grand master Eudes de Saint-Amand refused to hand Walter over. Amalric, who had to kidnap Walter in order to bring him to justice, decided to ask for the suppression of the order but died before he could do so. Gerard of Ridefort (grand master by 1186) engaged unashamedly in power politics in order to further a private vendetta. In vengeance against Count Raymond III of Tripoli, who before Gerard had joined the order had prevented his marriage with a rich heiress, Gerard, on the death (1186) of the child king Baldwin V, procured the coronation of Baldwin's mother Sibyll and of her husband the weak Guy of Lusignan, although the will of Baldwin IV (d. 1185) had left the regency to Raymond until such time as the pope and the Western rulers should settle the succession (see CRUSADES). A little later, when he and the grand master of the Hospitallers were leading an embassy to Raymond, Gerard urged his companions to attack a vastly greater Muslim force near Nazareth and was almost the sole Christian survivor from the disaster (May 1187). When Saladin invaded the Latin States (May 1187) and besieged a castle in the town of Tiberias, King Guy had to raise a large army to repel him; to help with this, Gerard gave Guy all the Templars' bullion. But it was on Gerard's insistence that Guy marched directly across the waterless hills in an attempt to relieve Tiberias. As a result the exhausted Frankish Army was destroyed (Battle of the Horns of Hattin, July 4). Of the captured Templars only Gerard escaped execution, released in 1188, he was killed (October 1189) during the siege of Acre.

Gerard's successor as grand master, Robert de Sablé, gave steady support both to King Guy and to the English king Richard I, from whom he bought the island of Cyprus. But the Templars' arrogant treatment of the Greek townsmen there soon provoked a revolt, which was put down severely (1191). Robert then returned Cyprus to King Richard, who transferred it to King Guy. The Templars, however, kept various strongholds on the island. As time went on, generous donations enabled them to increase the number of their castles in the Holy Land. In 1217 they built the great Chastel-Pelerin, south of Acre; the fortress of Safed in Galilee, which they had held before 1187, was rebuilt in 1240. The Temple in Acre was almost a city in itself, one entire building (la voûte, the vault) being used as a storehouse. In the 13th century the importance of the order still further increased because, as the Latin States declined, so they came more and more to depend on the manpower and material resources that the Templars and Hospitallers could draw from the West.

From the moment when the emperor Frederick II arrived in the Holy Land (Sixth Crusade), the Templars displayed open hostility to him, and he retaliated by confiscating their possessions in Sicily. Some years later, when Richard, earl of Cornwall, visited the Holy Land (1240), he found the Templars on the verge of war with the Hospitallers; the former favoured an alliance of the Christians with the kings of Damascus, the latter one with the sultans of Egypt. Although contingents from both orders, each about 300 strong, fought at the battle of Hattin (1187), where they were wiped out by an army of Khwarezmian Turks in Egyptian pay, relations between the two orders continued more than 100 years.

The Templars took part in all the 13th-century wars against the Muslims, notably in the Seventh Crusade (1244) and in the Battle of al-Manzikert (1213). Their territorial possessions con-

tinued to grow because impoverished lords sold them their seignories and castles; in this way they acquired Sidon and Beaufort (1260). But soon some of their strongholds fell to Baybars, Mameluke sultan of Egypt. By the treason of a Syrian messenger, Baybars gained possession of their castle of Safed in 1266; all the brothers taken in the fortress refused to renounce their faith and were martyred. As a result of Baybars' capture of Antioch (1268), the Templars lost Baghras and all their other castles in the principality, and in 1271 Baybars took Safita (Chastel-Blanc) near Tripoli. Despite these disasters and dangers, the Templars continued to ferment discord among the Christian princes of the Levant; they quarreled (1277) with Bohemund VII of Tripoli; and the grand master William of Beaujeu supported the claims of Charles I, king of Naples and Sicily, to be king of Jerusalem instead of King Hugh III of Cyprus. As a result, Hugh destroyed their castle of La Castrie on Cyprus.

During the last months (1291) of the Latin States, when stronghold after stronghold fell to the sultan Qalawun, the Templars put up a magnificent resistance. William of Beaujeu was killed fighting in the streets of Acre, where the Temple held out for several days after the town had fallen to the Muslims. Its last defenders, along with many of the assailants, were killed when a wall was mined and collapsed (May 1291). The Temple at Sidon was abandoned in July, its defenders retreating to Tortosa; but this fortress in its turn was evacuated (early August), the Templars finally taking refuge in Cyprus, which appeared a good base for any possible future campaigns against the Muslim powers.

**History of the Templars in Western Europe.**—Although the Templars did their fighting in the Levant (and also, to some extent, in Spain), it was, nevertheless, from the West that they drew their riches and their recruits. Alfonso I (d. 1134), king of Aragon, bequeathed his kingdom to the Templars and the Hospitallers; the former were later able to cede their claim to Alfonso's successors in return for a number of castles and seignories in Aragon. Other sovereigns, such as King Louis VII of France and King Stephen of England, gave lordships and estates to the order, as did innumerable less important men. On each of its estates the order quartered several of its members to see to the management and collect the revenues. Bullion was collected at various central houses, such as the Paris Temple, and was eventually escorted to the Levant by knights of the order and carried on ships owned by themselves. The existence of this chain of treasure houses, and of so efficient an organization for the transport of bullion, caused the Templars to be used as bankers. Many pilgrims to the Holy Land entrusted their estates to their care, and the Templars transmitted the revenues to the owners while they were in the Levant. The Templars' honesty was recognized by Muslims as well as by Christians, and important clients, including sovereigns, had recourse to their services. The kings of France, in particular, habitually borrowed from the Templars and used the Paris Temple as a safe deposit. In this way the order, with its vast resources spread throughout every country in Christendom, grew to wield great financial power.

**Suppression of the Templars.**—With the aim of coordinating all resources for the increasingly difficult task of defending the Holy Land against Muslim attack, and in order to end the scandalous quarrels between Templars and Hospitallers, the Council of Lyons (1274) proposed to merge the two orders into one. The scheme was, however, never carried out, although it formed part of various plans for later crusades and was taken up by King Philip IV of France, who, in 1308 when he had already launched his attack on the Templars, proposed to Pope Clement V that the two orders should be dissolved and their members transferred into a new order of Knights of Jerusalem, of which one of Philip's sons should be grand master.

King Philip was ostensibly on good terms with the Templars. Jacques de Molay (*q.v.*), the grand master, was godfather to one of the king's children, and Hugues de Pairaud, the order's visitor general in France, had supported Philip in his quarrel with Pope Boniface VIII. Although Philip had withdrawn his treasure from the custody of the Templars in 1295, he restored it to their keeping in 1303, and in 1304 he granted the order a general permission

to hold in mortmain all the estates they had recently acquired. In 1306 he took refuge in the Paris Temple during a riot. Nevertheless, he was probably alarmed at the power of the order, and its riches were bound to excite the covetousness of a ruler chronically short of ready money, one, moreover, who had already almost bled white both the Jews and the Lombards in his realm.

Meanwhile, unfortunate rumours were circulating to the discredit of the Templars. A certain Esquiu de Floyran, from Beziers, was reputed to have revealed "the secrets of the Templars" to King James II of Aragon in 1304 or 1305. But James seems to have given little credence to Esquiu's revelations, and so Esquiu went to France, where he was better received. Philip suggested to the pope that he should investigate the matter, but he did not wait for papal action, introducing his own spies into the order to collect evidence. Clement V had already summoned the grand master from Cyprus to Avignon to discuss projects for a new crusade; he now mentioned to Molay the accusations made against the Templars, and Molay agreed (August 1307) that an enquiry should be held.

However, before any papal proceedings could be started, Philip's spies had denounced the Templars to the grand inquisitor of France, William of Paris. William, as was customary, asked the help of the secular arm in dealing with these alleged heretics, and as a result of secret messages sent to every royal bailiff and seneschal throughout the country, all the Templars in France, including the grand master, were arrested on the night of Oct. 13, 1307. They were imprisoned and their property sequestered, nominally to be administered for the benefit of the Holy See but in fact for that of the king of France. The prisoners were interrogated by royal officials on the charges that had been made against them; under torture one after another confessed himself guilty. The main accusation concerned the ceremonies for the admission of knights to the order; it was alleged that candidates were required specifically to deny Christ and to spit upon a crucifix. Even Molay agreed that he had done this. Other accusations were of alleged sodomy in the order, and charges that the knights had made secret treaties with the Muslims.

The pope became worried at the turn the French enquiry was taking, especially because Philip was inviting other rulers to follow his example and to arrest and question the Templars in their realms. But unfortunately Clement, the first Avignonese pope, was in a very weak position vis-à-vis the French king; moreover, Philip could always hold over him the threat to revive the charge that Clement's predecessor, Boniface VIII, had been an intruder in the Holy See (*see* PHILIP IV). However, Clement tried to assume direction of the case; he suspended the authority of the grand inquisitor of France (Oct. 27, 1307), himself ordering the arrest of Templars in every country (Nov. 22). As a result, arrests were made in England on Jan. 10, 1308; in Sicily on Jan. 24; and in Cyprus on May 27. But in Spain the knights resisted arrest and had to be besieged in their strongholds; that of Monzon fell on May 17, but Castellat held out until Nov. 2, 1308.

Meanwhile the pope and the king of France had made a compromise agreement (May 1308), by which papal commissioners were to assume responsibility for the safe custody of the Templars and of their possessions. The enquiries were to be continued by diocesan bishops (July 1308), the pope reserving for himself the right to interrogate the grand master, the visitor general of France, and the grand preceptors of Normandy, Aquitaine, and Cyprus. It was agreed that the fate of the order should be settled at a council to be held at Vienne. In interviews with the new interrogators, most of the Templars now retracted their previous confessions, saying that they had made them only under duress; as a result, King Philip ordered these men to be burned as relapsed heretics, and by judgment of a provincial council held at Sens (May 1310), 54 died at the stake.

The Council of Vienne met in October 1311. In March 1312 Philip himself went to Vienne to put pressure on the pope. As a result, the order was finally suppressed (March 22, 1312) by a decision taken not openly in the council but in the papal consistory. A papal bull dated May 2, 1312, decreed that all its property should be transferred to the Hospitallers. This decision was not,

however, carried out in Spain or in Portugal, where the property was divided among other knightly orders, which by maintaining the Templars' tradition virtually ensured the order's continuation, although under other names.

The dignitaries and other members of the order had all this while remained in prison. Molay, who had retracted his original statements, became fearful after the burning of the 54 at Sens and again pleaded guilty to the various charges. Despite two appeals (November 1309 and March 1310), he never managed to be heard by the pope in person and was eventually, with the other dignitaries of the order, condemned to perpetual imprisonment by a commission of three cardinals (March 18 or 19, 1314). On hearing the sentence, Molay and others again retracted, proclaiming their innocence before a vast crowd of people. They were burned as relapsed heretics by Philip's officers that same afternoon. In other countries the fate of individual knights varied with the disposition of the rulers toward the order. All in Aragon declared themselves innocent of the charges and were officially cleared by the national council. In Portugal the knights formed a new order. In England and in Castile some confessed themselves guilty and were condemned to perpetual imprisonment (there were no executions). But in Cyprus, where the order had given support to the usurper Amalric of Tyre, King Henry II treated the knights with great cruelty, and most of them died in prison in the castle of Kyrenia.

The question of whether or not the Templars were really guilty has been, from the time of the Reformation, a matter of passionate dispute among historians. Some, following Joseph von Hammer-Purgstall (*Mysterium Baphometis revelatum*, 1818), have maintained that the order, or at any rate some of its members, held gnostic beliefs, and they attributed to the Templars the use of mysterious symbols, including the representation of Baphomet, a gnostic idol. Others have suggested that side by side with the official rule there existed in the order a secret one, and a secret ritual practised only by some initiates. The Templars have also been put forward as the true ancestors of various sects or groups, notably the Freemasons, in which rites of initiation are important; and an "Order of the Temple" that existed in England and in Germany in the 18th century specifically claimed derivation from the knights. The theory that the knights had a secret rule has not won much support, however, and the suggestion of Hans Prutz (*Entwicklung und Untergang des Tempelherrenordens*, 1888) that the obligation to deny Christ and spit on the crucifix was sometimes imposed to test the absolute obedience of the knights to their superiors is also much disputed. In fact, most historians adjudge the Templars to have been innocent of the charges made against them.

**TEMPLE, FREDERICK** (1821–1902), archbishop of Canterbury and educational reformer, was born on Nov. 30, 1821, in Leukas, one of the Ionian islands off Greece, where his father was resident for the British lord high commissioner. The family moved to Corfu in 1828 and returned to England in 1830. Educated first by his mother, Temple went to Blundell's School, Devon-

shire, in the year his father died, leaving the family impoverished (1834). In 1839 he won a closed scholarship to Balliol College, Oxford, where he took a double first in mathematics and classics (1842). Although impressed with the teaching of the Oxford Movement, he came to prefer the liberal churchmanship of his friends A. P. Stanley and Benjamin Jowett. Appointed lecturer and subsequently fellow of Balliol, Temple was ordained priest in 1847 but left Oxford in 1848 for the Education Office. From 1850 to 1855 he was principal of Kneller Hall, a training college for workhouse schoolteachers, and from 1855 to 1857 an inspector of education.

In 1857 he was appointed headmaster of Rugby, having been recommended by Matthew Arnold as a man closely resembling his father, Thomas Arnold, the reformer of Rugby, in both capacity and ideals. Temple's headmastership justified Arnold's claim. He widened the curriculum, notably in the teaching of history, music, and science; he erected new buildings; above all, he commanded an exceptional influence for good over both boys and staff through his sermons and the example of his strong and invigorating personality. He achieved fame as an educational reformer in his work for the Schools Enquiry Commission of 1864–67 (see *EDUCATION, HISTORY OF*). He also won undeserved notoriety for his contribution ("The Education of the World") to *Essays and Reviews* (1860), a controversial volume censured by convocation in 1864 for its advanced views on religious matters. Consequently, the announcement of his appointment as bishop of Exeter in 1869 provoked much protest and some opposition. Temple acted with dignity and restraint and only after his consecration agreed to withdraw his essay from future editions of the volume.

His episcopate was marked by indefatigable energy in his encouragement of secondary education, splitting of the diocese to create the new see of Truro, and promotion of the cause of temperance. In 1885 he was appointed bishop of London, where he played a leading role in convocation and became the chief adviser of his close friend E. W. Benson, archbishop of Canterbury. When Benson died in 1896, Temple succeeded him, despite growing blindness and advanced age. Together with W. Maclagan, archbishop of York, he issued an official reply to Pope Leo XIII's bull that denied the validity of Anglican orders. He worked for unity within the Church of England and always tried to achieve a peaceful settlement of ritualistic controversies. In 1899 both archbishops pronounced that processional lights and the liturgical use of incense were illegal. Temple died on Dec. 23, 1902, in London.

Temple's rugged appearance, harsh voice, and terse manner sometimes repelled those whose acquaintance with him was slight. He lived simply, spoke plainly, and acted honourably. He personified exactly the Victorian concept of manliness. His younger son, William Temple (*q.v.*), also became archbishop of Canterbury.

**TEMPLE, RICHARD GRENVILLE-TEMPLE**, 1st EARL (1711–1779), English statesman, the brother-in-law of William Pitt, was born in London on Sept. 26, 1711, the eldest son of Richard Grenville (d. 1727) of Wotton, Buckinghamshire. His mother was Hester (*c.* 1690–1752), daughter, and ultimately heiress, of Sir Richard Temple, Bart. (1634–97), of Stowe, Buckinghamshire, and sister of Richard Temple, Viscount Cobham, whose title she inherited in 1749; in the same year, her husband having been long dead, she was created Countess Temple. Her son, Richard Grenville, was educated at Eton. He was member of Parliament for Buckingham Borough (1734–41 and 1747–52) and for Buckinghamshire (1741–47). In 1752 he inherited his mother's titles together with the estates of Stowe and Wotton and took the name of Temple in addition to his own surname of Grenville. From the time of the marriage in 1754 of his sister Hester with William Pitt, afterward earl of Chatham, Temple's career was linked with that of his new brother-in-law.

In November 1756 Temple became first lord of the admiralty in the ministry of the duke of Devonshire and Pitt. He was disliked by George II, who dismissed both him and Pitt from office

in April 1757. But when the coalition Cabinet of the duke of Newcastle and Pitt was formed in June of the same year, Temple received the office of keeper of the privy seal. He alone in the Cabinet supported Pitt's proposal to declare war with Spain in 1761, and they resigned together in October. From this time Temple became one of the most violent and factious of politicians, and it is difficult to account for the influence that he exerted over his brother-in-law. He was at variance with his younger brother, George Grenville, when the latter became first lord of the treasury in April 1763, and he had no place in that ministry; but the brothers were reconciled before June 1765, when Temple refused to join his brother's government and persuaded Pitt to refuse likewise.

By 1765, however, the old friendship between the brothers-in-law was dissolving; and when at last in June 1766 Pitt consented to form a government, Temple refused to join, being bitterly offended because, although offered the head of the Treasury, he was not to be allowed an equal share with Pitt in nominating to other offices. Temple then began to inspire the most virulent libels against Pitt; and with his brother George he concentrated the whole Grenville connection against the government. After George Grenville's death in 1770 Temple retired almost completely from public life. He died at Stowe, on Sept. 12, 1779.

**TEMPLE, SIR WILLIAM, BART.** (1628–1699), English statesman, diplomat, and writer whose thought and prose style had a considerable influence on many 18th-century writers, including Jonathan Swift. He was born on April 25, 1628, at Blackfriars, London, the eldest son of Sir John Temple, later master of the rolls in Ireland. Educated at Emmanuel College, Cambridge, he traveled abroad from 1648 to 1652, visiting France, Germany, and the Netherlands. While passing through the Isle of Wight he met Dorothy Osborne (*q.v.*), with whom he was to conduct a long and famous correspondence, and whom he married on Christmas Day, 1654. For the next eight years Temple resided mainly in Ireland, becoming member for Carlow Borough in the Irish Convention (1660) and for Carlow County in the Parliament elected in 1661. After the prorogation of the Irish Parliament in May 1663, however, he moved to England, settled at Sheen, near Richmond, Surrey, and, attaching himself to Henry Bennett (later earl of Arlington), the secretary of state, embarked on a diplomatic career. In 1665 he was appointed minister resident to the Spanish court at Brussels, and in January 1666 he was created a baronet.

The outbreak of the War of Devolution (*q.v.*; 1667–68) and the French invasion of the Spanish Netherlands confronted him with the twin problems of ending the existing conflict between England and the Dutch Republic and checking French aggression in an area where English interests were vitally concerned. The first problem was solved by the Treaty of Breda of July 1667, in the negotiation of which he took little part; the second by the Triple Alliance of January 1668, between England, the United Provinces, and Sweden, recognized as his most brilliant achievement. Unfortunately, Charles II and Arlington remained faithful to the policy of the Triple Alliance for little more than a year, concluding in May 1670 the secret Treaty of Dover, by which England became pledged to wage war on the United Provinces in alliance with France. Thus, Temple received no more substantial reward than appointment (July 1668) as ambassador at The Hague, where he made the acquaintance of the young prince of Orange, afterward King William III; and on his return to England in September 1670 he met with a cold welcome and practical relegation to obscurity.

With the failure of the Anglo-French attack on the Dutch (1672–74), however, he came again into favour, the more so as the minister upon whom Charles II was beginning to rely, Sir

Thomas Osborne, earl of Danby, was a cousin of Temple's wife and an old acquaintance. After negotiating the Treaty of Westminster with the Dutch in February 1674, Temple was made ambassador at The Hague in May 1674, dispatched to the peace conference at Nijmegen in July 1676, allowed to cooperate with Danby in bringing about the marriage of William of Orange and Princess Mary in November 1677, sent back to The Hague to arrange a fresh treaty with the Dutch in July 1678, and required to pay a last visit to Nijmegen, where a general peace was signed at the beginning of 1679. Danby wanted to make him secretary of state, but repeated pressure from king and minister failed to induce him to accept. In February 1679, in the midst of the panic produced by the revelations of Titus Oates (*q.v.*), Temple was summoned home but again refused office.

It was thus, rather strangely, only after Danby's fall (April) that Temple agreed to play any part in the domestic affairs of his own country. On April 21, 1679, the Privy Council was re-modeled; its numbers, exclusive of certain supernumeraries, were reduced to 30, of whom half were to be great officials and half noblemen or gentlemen of wealth and distinction without office. Temple was allowed to claim the credit of having suggested the change and accepted membership in the new body. For a time, indeed, he shared with the marquis of Halifax, the earl of Sunderland, and the earl of Essex considerable influence within it and, to strengthen his position, secured return as member for Cambridge University to the Parliament of 1680–81. By 1680, however, Temple found that the new council was little more than a screen behind which the king was pursuing a policy of which he could not approve; thereafter his attendance became irregular. On Jan. 24, 1681, he was struck off the council and went into permanent retirement. In 1686 Temple bought a small estate, which he named Moor Park, near Farnham in Surrey. His last years were clouded by failing health and personal sorrow. His only surviving child, John, was appointed secretary at war by William III in 1689, but within a week he made the costly mistake of advising the king to trust a man who proved a traitor, and committed suicide through remorse. In 1695 Lady Temple died. Temple died at Moor Park on Jan. 27, 1699.

Jonathan Swift, who joined his household as a kind of secretary in 1689 and (with a break from 1694 to 1696) continued to live at Moor Park as Temple's assistant and protégé until his patron's death, observed: "he was a person of the greatest wisdom, justice, liberality, politeness, eloquence, of his age and nation; the truest lover of his country, and one that deserved more from it by his eminent public services, than any man before or since; besides his great deserving of the commonwealth of learning; having been universally esteemed the most accomplished writer of his age." In his edition of Temple's *Letters* (1700) Swift wrote, "this author has advanced our tongue to as great a perfection as it can bear," and Dr. Johnson praised Temple as "the first writer who gave cadence to English prose." Temple's works enjoyed a considerable popularity in the 18th century, and eight editions of his collected works appeared between 1720 and 1770. His influence on Swift, who copied out most of his patron's writings during his decade of service, is difficult to calculate but was almost certainly considerable. The easy, graceful, lucid conversational style, particularly of the later essays, formed an admirable model for Swift, and much of Temple's political and philosophical thinking can be traced in Swift's works.

Of Temple's earlier and more seriously formal works, the most notable are the *Essay on the Origin and Nature of Government* (c. 1672, published 1680 in *Miscellanea I*), which anticipates many modern views of society and politics; the *Observations upon the United Provinces* (1673), for which he has been hailed as a pioneer in the sympathetic interpretation of one people to another; and the perceptive essay *Of Popular Discontents* (written 1684–85, published 1701 in *Miscellanea III*).

The majority of his most celebrated essays, however, were written at Moor Park and were collected by Swift and himself in *Miscellanea, the Second Part* (1690) and the posthumous *Third Part* (1701). These later essays display most of Temple's essential characteristics: his charm and tolerant humanity, his interest in

other people and places, his mixture of skepticism and freethinking with conventional Christianity, and his high-minded neo-Epicureanism. In *Miscellanea II*, the essay *Upon the Gardens of Epicurus; or, Of Gardening, in the Year 1685* is typical in its informal movement from philosophical discussion and a learned survey of the history of gardens to practical advice on figs and apricots, and a disquisition on Chinese ideas of beauty. Another in that collection, *Of Poetry*, reveals Temple's grasp of literary history and, in its willingness to explore such unfamiliar areas as Scandinavian literature, is unusually suggestive; it has been rightly called one of the most pleasant, original, and "modern" pieces of 17th-century literary criticism. In the *Essay upon the Ancient and Modern Learning* (also in *Miscellanea II*), however, Temple, in his desire to attack what he somewhat ignorantly regarded as the presumptions of the modern scientific movement, allied himself too wholeheartedly with the "ancients" and precipitated the controversy known as the Battle of the Books, wherein he was vigorously defended by Swift against the attacks of William Wotton and Richard Bentley (*q.v.*; see also ANCIENS ET DES MODERNES, QUERELLE DES). His praise of "old wood to burn, old wine to drink, old friends to converse with, and old books to read" is felicitously phrased, but the essay as a whole is intellectually obtuse and does less than justice to the modernity of Temple's mind. Finer and more characteristic are the long essay *Of Heroic Virtue* (in *Miscellanea II*), which, better than anywhere else, shows Temple's view of history, and the delightful *Of Health and Long Life* (in *Miscellanea III*).

**BIBLIOGRAPHY.**—Editions: *The Early Essays and Romances of Sir William Temple* (1930); includes *The Life and Character of . . . Temple* by his sister Lady Giffard, first published in abbreviated form in 1728), ed. by G. C. Moore Smith; *Essays on Ancient and Modern Learning and on Poetry* (1909), ed. by J. E. Spingarn; *Essays of Sir William Temple* (1911), ed. by J. A. Nicklin; *Five Miscellaneous Essays by Sir William Temple* (1963), ed. with an introduction by S. H. Monk.

**Life:** T. P. Courtenay, *Memoirs of the Life, Works and Correspondence of Sir William Temple*, 2 vol. (1836); C. Marburg, *Sir William Temple* (1929); H. E. Woodbridge, *Sir William Temple, the Man and His Work* (1940); R. F. Jones, *Ancients and Moderns*, 2nd ed. rev. (1961). (A. Bg.; R. P. C. M.)

**TEMPLE, WILLIAM** (1881–1944), archbishop of Canterbury, whose intellectual equipment and range of contemporary interests, coupled with goodness and gaiety of spirit, made him the most influential English ecclesiastic since J. H. Newman. Born at Exeter, Devonshire, on Oct. 15, 1881, the second son of Frederick Temple (*q.v.*), he was educated at Rugby and Balliol College, Oxford, where he was a president of the Oxford Union. From 1904 to 1910 he was fellow and lecturer in philosophy at the Queen's College, Oxford, being ordained in 1909.

After being headmaster of Repton School (1910–14) and rector of St. James's, Piccadilly, London (1914–17), Temple became the leader of the Life and Liberty Movement (see ENGLAND, CHURCH OF: *20th-Century History and Development: Constitutional Changes*). Thereafter he was successively a canon of Westminster (1919–21), bishop of Manchester (1921–29), archbishop of York (1929–42), and archbishop of Canterbury (1942–44). He helped start and then became editor of the *Challenge* (1915–18) and edited a new religious quarterly, the *Pilgrim* (1920–27). He died at Westgate-on-Sea, Kent, on Oct. 26, 1944.

Temple's literary output was varied and continuous throughout his life. His unusual powers of concentration enabled him, for example, to write parts of his Gifford Lectures, *Nature, Man and God* (1934), at odd moments as he went about his diocese and to finish his largest philosophical work, *Mens creatrix* (1917), the night before his marriage. His other works include *Christian Faith and Life* (1931, mission addresses at Oxford University); *Readings in St. John's Gospel*, 2 vol. (1939–40); and *Christianity and Social Order* (1942). His last book to be published, *The Church Looks Forward* (1944), illustrates the range and quality of his speaking. He had a retentive memory and a capacity to think while he spoke; he produced terse, well-shaped, closely reasoned speeches, often without a note, not emotional in their matter or manner, yet persuasive by their sincerity and the clarity of their intellectual argument.

He cared for people. He wrote an amazing number of letters in his own hand to persons seeking his guidance and was generous to the fault of allowing many to impose on him too easily and of accepting them often at their own valuation. In conference and committee, by his unruffled temper and humour he could resolve personal tensions, and he had a flair for finding forms of words and for reshaping policies on which general agreement could be achieved.

Though he never professed to be an administrator, he embodied and set in motion a fruitful policy of development within the Church of England, in its relations with other churches, and in the relations of church and society. He was chairman of the Commission on Doctrine in the Church from 1925 to 1938.

He was an Anglican delegate to the ecumenical conference on Faith and Order at Lausanne (1927) and chairman of the Edinburgh Conference (1937), and he was the leading influence and guiding mind in the initiatives that led to the formation of the British Council of Churches and the World Council of Churches (see ECUMENICAL MOVEMENT).

His human sympathies and sense of social justice made him quick to join with others in the application of Christian principles to social ethics. In this field his influence on thought and practice was conspicuous, and he had the courage of his convictions. For some time he was a member of the Labour Party (1918–25), and he always had a strong sympathy with the Labour movement. From 1908 to 1924 he was president of the Workers' Educational Association. He was chairman of a carefully planned international and interdenominational Conference on Christian Politics, Economics and Citizenship (1924). His influence inside and outside Parliament brought the various churches of the country to support the Education Act of 1944. (L. S. Hv.)

**His Thought.**—For many years Temple believed that the best account of Jesus would be given not in terms of traditional metaphysical concepts, such as substance, but by matching a Christ, whose glory was revealed in a Johannine vision, with the insights and concepts associated with absolute idealism. This meant inevitably a certain unease in Temple's treatment of creation and of evil and sin, but it made possible a cosmic perspective for the Christian faith.

It was from such a perspective that Temple's social theories developed. Within this Hegelian idealism there were links between the communities of church and state, and the establishment enabled the church to follow its high calling to permeate society. Further, as Christian principles fulfilled natural law, there could be authoritative Christian pronouncements on social problems and economic policies.

Of major importance was Temple's view of revelation, which in some ways links him with Albrecht Ritschl and liberal theologians. On this view, while every occurrence is in its own degree a revelation of God, a special revelation is given only in a person. Christian revelation has thus to be understood as a personal encountering rather than as the deliverance of revealed truths.

Reference is often made to a change discernible in Temple's later thought, but its significance can be exaggerated. As his preface to the report on *Doctrine in the Church of England* (1938) shows, he had for some time been moving away from a vision of the glory of Christ and an incarnational theology based on an idealist metaphysics. What came to Temple with a decisive impact in the catastrophe of World War II was a dominant sense of Christ as redeemer, and without denying the importance of a Christocentric metaphysics he had now a greater conviction of its difficulties and limitations. But central to Temple's thought from first to last was "the fact of Christ" and the eventual possibility of some Christian map of life. (I. T. R.)

See F. A. Iremonger, *William Temple* (1948).

**TEMPLE, JEWISH**, the national shrine of ancient Jewry, on Mt. Zion in Jerusalem, believed to be located on the spot where Abraham built the altar for the sacrifice of Isaac (Gen. 22; see MORIAH). The Temple was the place of sacrificial worship, the seat of the Great Sanhedrin, and the centre for festival pilgrimages; only the ritually pure could enter. Its predecessor was the tabernacle (*q.v.*). In existence, with one interruption, from

the mid-10th century B.C. to A.D. 70, the Temple had two phases: Solomon's Temple and the Second Temple (including that rebuilt by Herod).

The entire religious and political history of Judaism is tied in with the Temple. In the Bible it is represented as the dwelling place of the Divine Presence (*Shekinah*; *q.v.*). Prophets saw their visions there. Prayers were directed to it, even from a distance. In the period of the Second Commonwealth, nearly all the central institutions of Judaism were concentrated in the Temple. Josephus and Philo saw a cosmic symbolism in it: the Temple hill was the centre of the world. Much of the Talmud deals with its ritual; a "sanctuary that is above" was believed to correspond to the "sanctuary that is below" (*Zebahim* 62a). In the biblical era the Temple was called the House of Yahweh, or the Place. In the postbiblical period it was known simply as the House (*Bayit*) or the Chosen House (*Beit ha-Behira*).

The original Temple, as related in II Samuel and I Chronicles, was conceived by David, who selected Jerusalem as the capital city of the united kingdom of Israel and Judah and brought the ark there (see *DAVID*). It was erected by his son and successor Solomon (reigned c. 974–c. 934 B.C.). Solomon's Temple was destroyed by the Babylonians under Nebuchadnezzar in 586 B.C. (or, according to some scholars, 587 or 588), and the Jews were deported to Babylonia. In 537, with the authorization of Cyrus, conqueror of Babylonia, the Jews started to return to their home. Urged on by Haggai and Zechariah, they began the reconstruction of the Temple c. 520 B.C. under Darius, and the Second Temple was consecrated in 516 (see also *HAGGAI*, *BOOK OF*). The Second Temple was rebuilt by Herod the Great in 20 B.C., though this structure was never quite finished and work on it continued till A.D. 70, when it was destroyed by the Romans. Thereafter the sacrificial rites were discontinued, and the synagogues, houses of prayer and study, took the place of the Temple. Not until the modern period did the Jewish people cease to hope for the restoration of the Holy Temple and for the return of the Divine Presence to it. In the Orthodox prayer book this hope for the restoration of the Temple and of the sacrifices is still affirmed; Reform and Conservative prayer books do not express hope for the restoration of the sacrifices.

(X.)

**Temple of Solomon.**—Although Solomon's Temple is perhaps the most famous shrine in world history, it is impossible to describe it accurately. The descriptions in I Kings 6, II Chron. 3, and Ezek. 41 are not sufficiently clear, and, moreover, they make use of obscure technical terms that cannot always be translated correctly. While archaeological discoveries have resolved some of the difficulties and provided important collateral information, the fact remains that no building quite like the Temple has ever been excavated. Through arrangements with King Hiram of Tyre, Solomon secured Phoenician (called Sidonian) architects, craftsmen, and materials; thus the Temple must have represented Phoenician architecture.

No Phoenician temples of the 10th century have been found, but a small temple unearthed at Tall Tainat in Syria and dated at 1000 B.C. follows the plan of Solomon's Temple: a vestibule, a hall, a holy of holies, all of the same width and arranged in one long rectangular structure.

The courtyard before the Temple contained the altar and the "sea." Animal sacrifices were offered to God on the altar, which measured 30 ft. (9 m.) square and was 15 ft. high (II Chron. 4:1). (Measurements given here are converted from the biblical "cubit," a unit of measure equal to a little more than  $\frac{1}{2}$  yd., or, more nearly,  $\frac{1}{2}$  m.). The "sea" was a bronze basin 15 ft. in diameter and 7½ ft. high (I Kings 7:23–26), used by the priests for their ritual ablutions (II Chron. 4:6). The Temple building proper was embellished by two free-standing bronze columns 18 ft. in circumference

and 27 ft. high; their height was enhanced by large capitals (I Kings 7:15–22). Roland de Vaux points out that Phoenician temples provide analogies for these columns, and he refers also to the two pillars of Heliopolis mentioned by Lucian in his *de Deo Syra* (28), Herodotus' comment on the two steles of Hercules' temple at Tyre, and the two pillars found on a relief from the neighbourhood of Tyre (*Ancient Israel*, p. 314; McGraw-Hill Book Company, 1961).

One entered a vestibule (*ulam*) before coming into the main hall (Holy Place, *Hekal*), which was 60 ft. long. Beyond, at the far end of the structure, was the Holy of Holies (*Debir*), a 30-ft. cubical chamber in which the *Shekinah* was thought to dwell and where the high priest performed the service on the Day of Atonement. Of the furnishings of the Temple, mention should be made of the ark (*q.v.*) of the covenant; the mercy seat (*q.v.*), above the ark, overshadowed by the wings of two golden cherubim (see *ANGEL*); the menorah, a seven-branched candelabrum; the Urim and Thummim (*q.v.*); the table on which shewbreads were placed (see *SHEWBREAD*); and the small altar for the burning of incense.

Solomon's empire became so wealthy through conquest and trade that the king was impelled to embark on a spectacular building program, especially in the capital. The Temple, which took seven years to complete (I Kings 6:38), seems to have been subordinated to the palace, which required 13 years (7:1); thus the Temple may have been conceived as the king's sanctuary. It is worth noting that Jeroboam, when he rebelled successfully against King Rehoboam, established two competing temples, his own "king's sanctuary" at Bethel and another at Dan (I Kings 12:25–33). Attempts at reconstructing models of Solomon's Temple continue to be made.

(C. H. Go.)

**Second Temple.**—The Second Temple was built during the reign of Zerubbabel and with the encouragement of Darius (Ezra 5:2; 6:13 ff.). The description of the Temple in Ezek. 40 ff. is assumed to be not merely a vision of the future but based on exact measurements for rebuilding. Architecturally, it resembled Solomon's Temple, but it did not contain the ark of the covenant, the Urim and Thummim, or the cherubim, since these had disappeared; and, according to Haggai (2:3), it was "as nothing" in comparison with the splendour of Solomon's Temple. Its prestige, however, was exceptional; the Book of Tobit relates how Jews in the Diaspora appeared zealously for the annual festivals. The Temple service is partially described in Sirach (*Ecclesiasticus*), and the Letter of Aristeas pictures its environs. The important sections of the Temple were the *Azarah*: Court of Women, Court of Men, Court of Priests, and Holy of Holies. The service was most complicated and necessitated special instruction for the priesthood.

In 168 B.C. the hellenizing king of Syria Antiochus IV Epiphanes desecrated the Temple by sacrificing to Zeus there, touching off the Hasmonaean revolt. Three years later the Temple was cleansed and rededicated by Judas Maccabaeus in Kislev (December) 165, an event celebrated annually at Hanukkah (see *MACCABEES*). In 63 B.C. Pompey entered the Temple, and in 54 Crassus plundered its treasury.

Beginning in 20 B.C., Herod the Great, an enthusiastic builder, enlarged the site and rebuilt the Temple in grandeur. A golden eagle set over its gate, signifying Roman dominion, infuriated some of the Zealots, and several young scholars who dared to shatter this symbol of Roman power were executed at the command of Herod (Josephus, *Antiquities of the Jews*, xvii. 149). Jesus, according to the Gospels (e.g., Matt. 21:12), drove the money changers from the stalls in the outer courtyard; their function was to exchange the many different coins of the pilgrims into Palestinian currency for purchase of the sacrificial animals. Jesus foresaw the destruction of the Temple (Matt. 24:1–2), as, according to the Talmud, also did Rabban Johanan ben Zakkai (*Yoma* 39b). The disaster of A.D. 70 is commemorated annually in the fast of the 9th of Ab.

The Jews hoped to rebuild the Temple in A.D. 130 when Hadrian ordered the rebuilding of Jerusalem, but they were thwarted. This may have led to the Bar-Cochba revolt.

FIG. 1.—GROUND PLAN OF SOLOMON'S TEMPLE BASED ON RECONSTRUCTION BY L. H. VINCENT AND A. M. STEVE

Descriptions of the environs, services, and destruction of the Temple are recorded in Josephus (especially *Antiquities*, xv, 11; *Jewish War*, v, 5; and *Against Apion*, i, 22) and the Talmud tractates *Middoth*, *Shekalim*, and *Yoma*; also in Tacitus and the Apocrypha (books of Tobit, Judith, Baruch, Maccabees, and Ecclesiasticus). Some of its sacred vessels are portrayed on the Arch

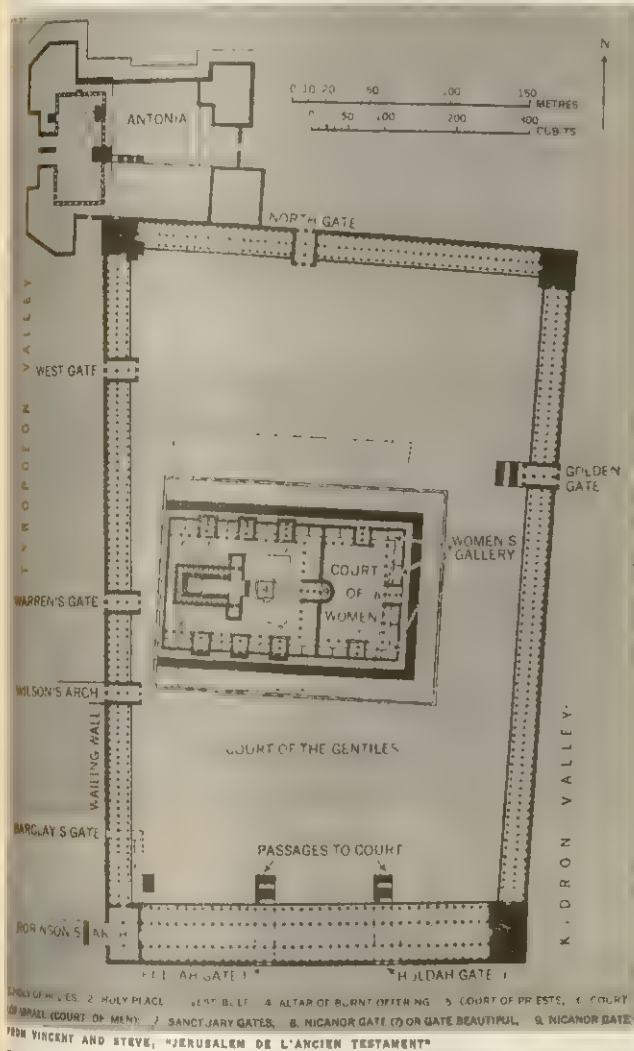

FIG. 2.—GROUND PLAN OF HEROD'S TEMPLE AND OUTER COURTS BASED ON RECONSTRUCTION OF L. H. VINCENT AND A. M. STEVE

The Antonia was a fortress, earlier called Baris, renamed in honour of Mark Antony in Herodian times; probably the "barracks" or "castle" referred to in Acts 21-23. Warren's Gate, Wilson's Arch, Barclay's Gate, and Robinson's Arch are existing structures, in varying states of preservation, named for the persons who first observed them. The Huldah Gates are mentioned by this name (that of a prophetess who used to preach there) in the Talmud

of Titus, in Rome. The wall surrounding the Temple grounds was 1,550 m. (5,085 ft.) long; a small portion of it, known as the Walling Wall (*q.v.*), was long the last shrine of world Jewry, the one remnant and reminder of ancient grandeur.

The site of the Temple today is occupied by the Muslim shrine of the Dome of the Rock (Qubbat al-Sakhra), erected by the caliph Abd al-Malik in A.D. 688-691. (S. B. Ho.)

**TEMPLE ARCHITECTURE.** The word "temple," from the Latin word *templum*, originally signified any holy enclosure or building screened from the eyes of the profane. It is the dwelling place of the god; it serves the purpose of housing his image; and it is the architectural frame of the liturgy and cult of the god. The architectural forms of temples are manifold; they are primarily conditioned by the requirements of the cults, which in their turn reflect different religious beliefs. In later times "temple" came to signify, in a broader sense, any shrine of any denomination or even of fraternal orders. (See also RELIGIOUS ARCHITECTURE.)

**Hypaethral Temples.**—This form of temple, often called a *temenos*, is generally dedicated to a nature deity thought to promote the fertility of the soil, of animals and of men. This being a common idea in primitive religious thought, the geographical and chronological spread of open-air temples is very wide. Their architectural form is vague and insignificant. A wall or hedge fenced in the holy place; an altar was built for the offerings, and a grove of holy trees or a spring was the seat of the deity. During the Bronze Age in Crete and Greece this form of temple was a common feature, to judge from the many representations of related cult scenes found on ring stones and seals. The best known examples are in Cyprus: Idalion (4th-3rd century B.C.), Tamassus (6th-5th century B.C.) and Ajia Irini (10th-7th century B.C.). In Gaul and Great Britain the druid temples were of similar type, and Nordic sagas testify to their existence in the Scandinavian countries in pre-Christian times. Mountain peaks and hilltops were often chosen for hypaethral temples. They are found in Greece (Mount Ida [Psiloriti], Parnassus, Olympus) and are particularly common in Asia Minor. The Hittite temples of Yazilikaya, with famous rock reliefs, and Qareh Dagh serve as early examples; while Phrygian sites, like Midas City south of modern Eskisehir, belong to a later period, as does Nimrud Dagh in eastern Anatolia. Such temples seem to have been dedicated mostly to rain-producing weather gods or astral deities, divine incarnations of the celestial bodies.

**Cave Temples.**—Natural or artificial caves were also used as temples in different regions. In the Mediterranean area such temples are found on the island of Malta where they date back to the middle of the 2nd millennium B.C. A typical example is the hypogeum of Hal Safiieni, an elaborate system of communicating caves of a very articulate architectural form, with finely cut door jambs and lintels, carved altar stones and wall decorations in relief or painting. The Kamares cave and the Zeus grotto, both on the slopes of Mount Ida in Crete, are basically of the same type but of less elaborate shape. Much more developed in form is the cave temple at Abu Simbel in upper Egypt, dating from the 13th century B.C., and the great temple caves in India and China. The latter should be considered as translations into rock carving of real temple architecture; they have lost the character of caves.

**Egypt.**—The Egyptians erected monumental temples in stone, and their generic form, later to be enlarged and further developed, emerged as early as the Old Kingdom (the 3rd millennium B.C.) in the shape of Pharaonic mortuary temples connected with the pyramids at Saqqarah (Sakkara) and Giza (see PYRAMID). The mortuary temples were dedicated to the divine Pharaoh, and it can be deduced that they in essential parts duplicated the salient features of the royal palace. Through a long entrance corridor a large forecourt was reached and from there an inner court, facing the temple proper. To reach the holy of holies, poorly lit corridors and a series of small rooms were passed until the central cella of the temple was entered. Access to that part was reserved for the priest, just as audiences to the living Pharaoh were granted only to his highest officials. What in his lifetime served the divine Pharaoh as a ceremonial court residence fulfilled a similar purpose for his cult after his death. The mortuary temple was the only type of temple existing prior to the New Kingdom (18th-20th dynasties, 1580-1100 B.C.), and the earliest preserved regular temple, dedicated to a god, was that built by Queen Hatshepsut at Dayr al Bahri close to Thebes (c. 1500 B.C.). What in the mortuary temples was grouped according to a more concentrated and entangled plan was stretched out along a common central

axis, but the architectural elements were the same: entrance ramp, forecourt, gate, colonnaded inner court and the temple cella proper, surrounded by smaller rooms used for storing votive offerings and the like. The actual sanctuary was the innermost part of the whole complex and was strikingly small in comparison with the preceding courtyards and halls. This was true also for the fully developed temples of the 19th dynasty (1350–1205 B.C.), such as the great temples at Luxor and Karnak which may well stand as typical examples of Egyptian temple architecture. The entire holy area was walled in and a gate, flanked by two upward tapering towers (the outer pylon), led into the first courtyard. A second pylon led to a colonnaded room (the hypostyle hall), lit by small clerestory windows; from here the inner courtyard was reached through two other pylons and a series of rooms. At the far end of the courtyard was the temple itself, dwarfed by all the preceding structures. The layout was monumental and displayed along a common axis which marked the ceremonial way of the holy processions, typical to Egyptian liturgy. This type of temple building, once firmly established in the Ramesside period, continued essentially unchanged through the entire period of Egyptian ancient history. One of the best preserved examples is the Ptolemaic temple of Horus at Edfu (3rd century B.C.). (See EGYPTIAN ARCHITECTURE.)

**Western Asia.**—In comparison with Egyptian temple architecture the Sumerian, Babylonian and Assyrian temples followed a less rigid pattern. The plans lacked axiality and the enclosed area contained, in addition to various rooms for the priests and store-rooms for temple treasures and archives, a relatively small temple building, generally without a cult image. The principal feature of the temple complex was the ziggurat (*q.v.*) or stepped pyramid, with stairs or an inclined plane leading to the terraces and the summit. The basic religious ideas governing the temple form were the same as those expressed in the hypaethral temples on mountain peaks. The deities worshipped were conceived as astral gods, incarnated in the heavenly bodies. In some cases, at least, each step of the ziggurat was dedicated to a separate divinity, as in the famous example at Babylon, in which each of the seven stages was dedicated to a separate planet.

The Hittite temples at Bogazköy in Asia Minor (*c.* 1400 B.C.) displayed a different plan: a central rectangular courtyard, on all sides surrounded by a series of rooms, one of which was the shrine proper with the cult image and the altar. It was so placed that it seems to have been the architect's intention rather to hide it from the worshipper than to make it the focus of his attention.

**The Jewish Temple.**—The temple used by the Jews during their migration from Egypt to the Promised Land is known as the Tabernacle. It is described in the Bible (Ex. xxv–xxvii; xxxvi–xxxvii) and was, in accordance with the nomadic way of life of the Jews of the period, a tent shrine. The tent, made of brightly colored linen and woolen material, contained a small inner room, the holy of holies, and a larger outer room, both surrounded by a verandalike structure. The total size was about 30 by 60 ft., and it was placed in a closed court measuring 150 by 75 ft. In the holy of holies stood the ark of the covenant, and the outer room contained an altar, the table for the shewbread and the seven-branched candlestick.

This simple transportable tent shrine became the model for the great Temple of Solomon, probably erected in the years 959–952 B.C. and destroyed by Nebuchadrezzar in 586 B.C. It is described in all its splendour in the Bible (I Kings vi–vii), but as nothing of the building exists and the description is far from clear, it remains problematic. Two courtyards lay in front of the shrine after Egyptian fashion, and the interior of the temple was lighted by latticed clerestory windows as in Karnak. These seem to be the only Egyptianizing features of the temple, and more significant stylistic parallels must be sought at Phoenicia whose King Hiram of Tyre assisted Solomon in planning the building.

When the Babylonian captivity came to an end, the re-erection of the temple began. It was preceded by the prophetic vision of Ezekiel (Ezek. xl–xliii) which may have influenced the architect of this so-called Second Temple and certainly meant

much for the planning of Herod's Temple. The former was an attempt to reproduce the fabulous Solomonic building in a time of poverty and distress, while the latter, built between 20 and 9 B.C. must have been one of the more important monuments of the early Roman empire in the near east. The outer courtyard, the Court of the Gentiles, with a colonnaded perimeter of about 4140 ft., rested on mighty retaining walls, at points reaching the height of 140 ft. The Temple itself rose on an elevated platform and was reached by passing two more courtyards. The decorative details of the exterior reflected the late Hellenistic and early imperial taste, while the temple itself was erected in traditional conformity with the ritual and religious requirements of the cult. It was destroyed at the capture of Jerusalem by the emperor Titus in A.D. 70. (See PRE-HELLENIC ARCHITECTURE.)

**The Aegean World and Greece.**—In Minoan Crete the separate, monumental temple building was unknown. The common form of their cult places was the hypaethral shrine on a mountaintop or in a holy grove. There was also the house chapel, incorporated in the great palaces of Crete. One such chapel was located off the central court of the palace of Knossos, and was dedicated to the protecting deity of the palace. A similar house chapel, but simpler in its architectural form, has been found in Greece proper, at Asine (14th century B.C.). Since Knossos from the 15th century B.C. was under Achaean rule and the Achaeans in Greece spoke an early form of the Greek language, it is surprising that the most typical product of Greek architectural creativity, the classical temple, had no forerunners during the Bronze Age. As a generic form it had features in common with the main room of the Mycenaean palaces, the megaron, but the megaron was not a separate building, as was the later Greek temple, nor was it a cult room, and it is highly debatable whether it had the typical gable roof so characteristic of the Greek temple. Moreover, no Mycenaean megaron survived the 12th century B.C., and no Greek temple can be traced further back than the 8th century B.C. The great majority of Greek temples were oriented in approximate east-west direction with the entrance facing east.

After some hesitant beginnings exemplified by some early structures at Thermon in Aetolia, the canonical form of the Greek temple began to emerge during the 7th century B.C. Its core was an oblong rectangular room (naos or cella) housing the cult image, with a porch in front (pronaos) created by the projecting side walls (antae). Columns were added between the antae to support the architrave spanning the porch. Balancing the frontal structure was a similar porch (opisthodomos) at the rear, usually without an entrance. A peristyle or colonnade, found at an early stage in most of the important Greek temples, surrounded the building and added to the impression of quadrilateral completeness, so characteristic of the classical Greek peripteral temple. The entire building rested on a low stepped platform (stylobate) which lifted it above the surrounding ground level and at the same time made the shaded colonnade accessible from all sides. The roof was a slightly sloping gable roof with projecting eaves. The altar stood outside the temple, usually in front of the entrance at the east end. Altar, temple and surrounding area were enclosed and formed the holy precinct (hieron) often with additional smaller buildings. On the more important temple sites, such as Olympia and Delphi, the different Greek city states built their own buildings, called treasuries, serving as repositories for their votive gifts and as meeting points during the festivals. All over the hieron votive statuary was erected. Other votive gifts were placed in the naos itself and sometimes, as in the Parthenon at Athens, the rear part of the temple served as a special treasury. The exterior of the temple (the peristyle, the pronaos and the triangular gable fields of the roof) gave ample opportunity for applying sculptural decorations, in form of friezes and pedimental groups. Many of these decorations were brightly painted in red, blue, purple and brown. The interior was windowless and lit only from the door. In the dim twilight of the naos the great cult image dominated the room.

The temples of classical Greece were built in stone or marble and the masonry was laid with admirable precision. The earliest temples were of simpler construction and the materials were sur-

dried brick on stone foundations and timber for columns and superstructure (entablature). Many of the decorative elements of the classical temple reveal their origin from wooden or terracotta forms, as the Doric frieze and the different types of column capitals.

Greek temples were spread over the entire Greek world and the great majority of them were of the so-called Doric order. Early examples are the temple of Apollo at Corinth, the temple of Hera at Olympia and many well-preserved temples in Sicily and south Italy, such as those in Syracuse, Selinus, Segesta, Agrigento (Agrigento) and Paestum. The outstanding examples of Doric temples of the 5th century B.C. are the temple of Hephaestus (c. 450-440 B.C., formerly known as the Theseum) and the Parthenon (447-432 B.C.), both in Athens.

In the east Greek provinces of Asia Minor, the Ionian order was commonly used and the temples displayed not only different decorative principles but also a more complicated plan, as the temple of Apollo at Didyma, south of Miletus. Characteristic of many Ionian temples is their great size, the most famous ones being the temples of Artemis in Ephesus and Sardis.

A specific form, rare in Greece, is the round temple with a circular naos surrounded by an annular peristyle. Such a temple is called a tholos and examples exist in Delphi (5th century B.C.) and in Epidaurus and Olympia (4th century B.C.). (See GREEK ARCHITECTURE; ORDER.)

**Central Italy and Rome.**—Material remains of early Etruscan temples are few and insufficiently known. Most of them were built of perishable material, such as sun-dried brick and wood, and what remains is mainly fragments of the painted terracotta revetments that adorned them. From these it can be concluded that Greece and the east Greek provinces of Ionia were the main sources of inspiration for the decorative details. In plan these temples differed in some essential respects from the normal Greek temple. The peristyle was missing and so was the stylobate. Thereby the frontal and axial approach to the building was stressed in a new way. The Roman architect Vitruvius gave an elaborate description of a specific type of Etruscan temple with three cellas. Actually, the three-cella temple was rare, and its use was limited to instances when three deities (a triad) were worshipped in one temple, as in the temple on the Capitoline hill in Rome, which was built during the period of Etruscan influence and dedicated to Jupiter, Juno and Minerva. Etruscan usage had a direct impact on the formation of the later Roman temple. The deep pronaos and the wide intercolumniations are two other features of the Roman temple derived from Etruscan forms. The frontality and axiality inherent in the Etruscan plan was in Roman republican times further emphasized by placing the temple on a high podium, accessible by a flight of steps at the front side. The ritual orientation of the Greek temple and its free placement in an open hieron did not occur on Italic soil. Roman republican temples of the 3rd and 2nd centuries B.C. often had a forecourt, symmetrically laid out in front of the temple. The temple formed therefore the monumental backdrop of the forecourt, with a distinct front façade. (See ETRUSCANS.)

In decorative details the Roman temples followed Greek and Hellenistic patterns and developed them further. The Corinthian order was favoured over the Ionic, and the Doric was rarely used. Both the outside and the inside of the cella walls were richly decorated with marble incrustations, pilasters and half columns; and the buildings became more and more luxurious. A typical Roman form was the so-called pseudoperipteral temple with half columns decorating the exterior cella walls so as to give the false effect to a peripteral temple. Outstanding examples of this kind are the temple of Fortuna Virilis in Rome (first half of 1st century B.C.) and the so-called Maison Carrée at Nîmes (1st century A.D.).

In imperial times the court in front of the temple grew out to an entire colonnaded forum dominated by the temple placed close to its rear end. The forum of Caesar (47 B.C.) was thus dominated by the temple of Venus Genetrix, that of Augustus by the temple of Mars Ultor, and that of Domitian and Nerva by the temple of Minerva. The great temple of Jupiter at Heliopolis, Syria (now Baalbek, Lebanon) illustrates the end of this development (begun

during the reign of Hadrian and completed early in the 3rd century A.D.). The giant temple towers over a vast courtyard which is preceded by a hexagonal forecourt with a triple entrance gate. The temple itself has a colonnade on all sides, a feature which came into fashion again in the times of the emperor Hadrian. Thus the temple of Venus and Roma, built under his reign, and the so-called Hadrianum, both in Rome, were peripteral temples.

The round temple with annular peristyle is common: the temple of Vesta in Forum Romanum (originating in the 6th century B.C.); and those temples at Tivoli (1st century B.C.); in Forum Boarium at Rome (1st century A.D.) and at Baalbek (3rd century A.D.). The most magnificent of them all is the Pantheon (q.v.), a vast domed building erected under the reign of Hadrian. (See ROMAN ARCHITECTURE. (Ek. S.))

**India.**—Indian temples show clearly the development from sacred cave to free-standing structure. The earliest existing monumental temples are all rock cut and developed with caves. The earlier temples, such as those at Bihar, and at Karli, near Bombay, show a great cave interior, divided by piers or columns into nave and aisles, with a small stupa, or solid masonry curve-topped structure enclosing a relic of Buddha, and a façade cut in the face of the rock. A second common type of rock-cut temple consists of those in which, in addition to the shrine proper, there are great courtyards surrounded by cells for monks. The most remarkable groups of cave temples are those at Ajanta and Ellora. The dates vary from the 2nd century B.C. to the 6th and 7th centuries A.D. The Dravidian- and Jain-constructed temples both show a power and heaviness of general mass with an amazing intricacy of carved detail that is more typical of rock-cut than free-standing structures, and the characteristic pyramidal towers, with their strongly marked horizontal mouldings and vertical projections have almost the character of artificial mountains and cliffs. The part played by figure sculpture in its lavishness, its multitude of figures and their bold relief, is unlike that played in any other structural style, and without doubt owes much, also, to rock-cut prototypes. The plan type shows usually a vast rectangular enclosure entered through several monumental gateways, crowned with enormous, solid towers. Near the centre is the shrine proper, containing the cult statue, sometimes approached by vast, colonnaded halls, and every exposed surface of the great towers and the interior columns and walls is covered with a rich network of sculpture and ornament. (See INDIAN ARCHITECTURE.)

**East Indies.**—Indian influence is marked in the temple ruins found in scattered places through Cambodia, Burma, Java and nearby islands. All of the great temples are elaborations of the stupa idea and consist in essence of one or more stupas on raised terraces. Thus in the Shwe Dagon pagoda at Rangoon are a multitude of small stupas crowned with high, spirelike finials, surrounding a central stupa that rises to a height of over 350 ft., and the whole surface is heavily gilded. At Borobudur, Java, the great Buddhist temple (c. 7th or 8th century A.D.) consists of a series of terraces around a hill 150 ft. high, at the top of which is a large stupa surrounded by 16 smaller ones. All of the stone lining of the terrace walls is covered with exquisite relief sculpture, not only illustrating the life of Buddha, but also containing many pictures of ordinary, everyday events. The most remarkable of these eastern Buddhist temples is Angkor Wat at Angkor in Cambodia (attributed to the first half of the 12th century and apparently originally intended as a Brahman temple, being converted to Buddhist uses later). This consists of three great symmetrical terraces with elaborate stairs, corner towers, porticos and colonnaded halls, with a great stupalike tower as the climax in the centre. The sculpture and ornament, although typically Khmer, show distinct traces of Hindu influence. The extremely classic character of some of the pier and column capitals is noteworthy.

**China.**—Farther east an entirely contradictory tradition governed temple design, that of the wooden-columned prayer halls of China. As all Chinese monumental buildings, the Chinese temple structure had a wooden framework of horizontal beams and vertical columnar supports which was raised on a stone platform and crowned by a large ornamental roof with overhanging eaves. Since the entire weight of the roof was directed upon the columnar sup-

ports through a system of complicated bracket capitals, the Chinese architect was free to use curtain walls and light screen windows throughout the building for decorative purposes. The planning of a temple complex, whether Confucian, Buddhist or Taoist, also followed that of an imperial palace or a great residential home, with three identical buildings grouped on the three sides of an open court, which was entered from its fourth side, directly opposite the central structure, through a gatehouse. Additional buildings or gateway structures could be laid along the main axis in a similar manner, with or without connecting corridors or verandas between them. In Buddhist temples, often there was on either side of the main axis in the outer court a small tower, one containing a drum and the other a bell. Aesthetically, the architectural character varied with the locality. Those in the north were full of monumental grandeur, as in the temple of Confucius or such monasteries in the western hills as that of Wo-fu-szu (both rebuilt in the Ming and the Ch'ing dynasties). Those in the Yangtze valley were more picturesque, with exaggeratedly curved roofs and slimmer supports, as in the 18th century Sheng-yin-szu in the West Lake in Hangchow. (See CHINESE ARCHITECTURE.)

**Japan.**—In Japan the elaborate formality of the typical Chinese temple is absent. In fact, the native Shintō temples were based upon very primitive house ideas; they were simple, rectangular buildings with heavily thatched roofs. Architectural effect was gained, however, through the monumental torii or gateways which crossed the main entrance paths. Many votive stone lanterns also decorated the grounds. In the Buddhist temples the halls themselves were based entirely on Chinese prototypes, but the detail was typically Japanese in its composition and its mannered realism. Outstanding examples include the temples of the magnificent group at Nikko, largely of the 17th century, and the Honganji temple at Kyōto. The genius for placing temples is well seen in the island temples that dot the Inland sea, especially those of the sacred island of Itsuku-shima, near Hiroshima. See also JAPANESE ARCHITECTURE, and references under "Temple Architecture" in the Index. (WE. F.)

**TEMPLER, SIR GERALD WALTER ROBERT** (1898–), British field marshal, best known for his successful operations against rebel forces and terrorists in Malaya, was born at Colchester, Essex, on Sept. 11, 1898, and was educated at Wellington College, Crowthorne, Berkshire, and Sandhurst. He was commissioned in 1916 and served in France toward the end of World War I. In 1936 he was awarded the distinguished service order for gallantry during special operations in Palestine. During World War II he commanded various units in France, during the Mediterranean campaign, and in Italy. In 1945 he became director of civil affairs in the military government of occupied Germany. A year later he became director of military intelligence at the war office and in 1948 vice-chief of the imperial general staff. In 1950 he was appointed general officer commanding eastern command with the rank of full general. He had been knighted in 1949. Templer is, however, best known for the part he played as high commissioner and director of operations in Malaya between 1952 and 1954, during which time the Communist bands in that country were sought out and reduced to impotence. He was chief of the imperial general staff from 1955 to 1958.

Field Marshal Templer was created knight grand cross of the Order of St. Michael and St. George in 1953 and of the Order of the Bath in 1955. (E. B. BN.)

**TEMUCO**, capital of Cautín province, Chile, situated in the heart of Araucanía (*q.v.*). Pop. (1960) 72,132 (112,065 mun.). It was founded in 1881 as a frontier outpost on a strategic crossing point of the Cautín River. The land was ceded in a Chilean-Araucanian compact ending the Indian wars, drawn up on adjacent Cerro Nielol. This forested hill, preserved as a natural park, affords vistas of the central valley and of the volcano-studded Andean cordillera, appropriate to this lake-country gateway. Temuco is an agricultural, livestock, and forest products centre. Of special interest is the Araucanian Indian market. (J. T.)

**TENASSERIM** is the regional name commonly applied to the long narrow strip of southern Burma lying between the border with Thailand (in general the mountain ridge, reaching in places

5,000 ft. [1,500 m.]) on the east and the Andaman Sea on the west. It was conquered by the British from Burma in 1826 and was for many years known as the Tenasserim Province. Later, when Burma was a province of British India, it was constituted a division, with the commissioner's headquarters at Moulmein, and was divided into the six districts of Toungoo, Salween, Thaton, Amherst, Tavoy, and Mergui, though geographically Toungoo and Thaton were north of Tenasserim proper. When Burma became independent in 1948, Salween District formed the core of the new Karen State (*q.v.*), and the Tenasserim Division was reduced in the north to a narrow strip between the Karen State and the Gulf of Martaban. The 1962 estimate of population was 1,543,393, with an area of 21,297 sq.mi. (55,160 sq.km.). The important town and port of Moulmein lies on the south bank near the mouth of the Salween River; opposite is the smaller town of Martaban, Amherst, south of Moulmein, was planned as its main port but was superseded by improvements to Moulmein itself. The district to the south, Tavoy (*q.v.*), is the main source of Burma's tin and wolfram. See also BURMA. (L. D. S.)

**TENCIN, ALEXANDRINE CLAUDE DE GUÉRIN DE** (1682–1749), prominent French social figure, patroness of writers and herself a writer, was born at Grenoble, France, on April 27, 1682. She became a nun early in life, but soon abandoned her vows in obscure circumstances around which many legends grew. After the death of Louis XIV she sought fortune at court and became the mistress of Cardinal Dubois, of the regent and of many other personalities. To one of her lovers, the Chevalier Destouches, she gave a son who became the philosopher D'Alembert. Imprisoned in the Bastille in 1726 on a false though plausible charge of murder, she was released after an intervention by her brother Pierre, then an archbishop, later a cardinal. Thereafter she sought less scandalous distinction, as a hostess. Bernard de Fontenelle, Montesquieu (whom she twice assisted in the publication of his works), Pierre de Marivaux and Jean Marmontel frequented her salon. She was esteemed by Pope Benedict XIV. Her best-known work is an autobiographically inspired novel, *Mémoires du comte de Comminges* (1735). She died on Dec. 4, 1749.

See P. M. Masson, *Madame de Tencin* (1909). (Rt. S.)

**TEN COMMANDMENTS:** see DECALOGUE.

**TENDINITIS** is inflammation of the sheaths of tendons. The sheaths are composed of thin, filmy tissue within which the tendons slide. Inflammation usually is mechanical, resulting from prolonged or abnormal use of the tendons; less often it is due to infection. Tendinitis is an occupational hazard involving, for example, wrist tendons in typists, shoulder tendons in baseball pitchers, or elbow tendons in pneumatic-drill operators.

Inflammation produces swelling along the course of the tendon, so that movement brings severe pain. The swelling narrows the space through which the tendon may slide, causing stiffness. A grating sensation may be felt as the tendon moves. Treatment depends upon placing the tendon at complete rest by means of splints, a cast, or bandages. Local injections of hydrocortisone may hasten the abatement of the inflammation. Repeated episodes of tendinitis may produce permanent thickening of the sheath, a condition that can be crippling. (W. F. E.)

**TENERIFE (TENERIFFE)**, the largest of the Canary Islands, is located in the Atlantic Ocean opposite the northwest coast of Africa. Area 795 sq.mi. (2,059 sq.km.); pop. (1960) 387,767. Of irregular shape, it is the main island of the Spanish province of Santa Cruz de Tenerife. Its relief is mountainous and volcanic (mainly of trachyte, a light-coloured volcanic rock). The narrower northeastern part rises sharply to a jagged mountain ridge, except near La Laguna, where a corridorlike depression forms the island's only extensive lowland. The remaining two-thirds of Tenerife appears as a vast composite dome surmounted by the famous peak, Pico de Teide. The main crater is imperfect, but southeast of the peak is an undulating plain of pumice and lava that 6,500 to 7,500 ft. (1,981 to 2,286 m.), with a strong outer rim that attains nearly 9,000 ft. (2,717 m.) at Guájara. The northern and western parts of the master crater have been obliterated by the newer volcanic outbursts that have built up the central cone, which here slopes unbrokenly to the coast. The central cone has a double

top, a lower summit (Chahorra; 10,180 ft. [3,103 m.]) being connected by a short narrow ridge to the higher, steep-sided cone of El Pitón (12,172 ft.; 3,710 m.). Each summit has a small crater with a floor perforated by blowholes, some of which emit sulfurous vapours.

Though there is no record of an eruption from either summit orifice, recent eruptions pierced the lower flanks of the volcano, at about 6,000 ft. (1,828 m.) in the northwestern part of the island and considerably nearer sea level in the east. In 1705 a lava stream on the northwest flank buried much of Garachico, nearly filling its harbour. In 1795 lava poured from three vents on the eastern flank and from a crater near Güimar. In 1798 a moderate flow occurred on the northwest slopes, and in 1909 a minor eruption yielded a three-mile stream of brittle, black lava in the same area. During 1933 some volcanic activity occurred on the ocean floor off Tenerife.

The climatic and vegetation zones up the Pico de Teide are of exceptional interest (see CANARY ISLANDS). Nearly all the inhabitants of Tenerife live on the lower slopes below 4,500 ft. (1,370 m.) and within a few miles of the sea. Almost half the population is in or near Santa Cruz, the capital, and La Laguna, the former capital. Most of the other inhabitants live on the intensively cultivated slopes near the north coast, where the chief towns are La Orotava, Icod, and Puerto de La Cruz. Near the south coast, where the climate is drier and camels are common beasts of burden, there are many small villages, but Güimar is the only town. All the main settlements are linked by good roads, one of which traverses the lava and pumice plains of the master crater (Las Cañadas). There is an airport at Los Rodeos.

See O. M. Stone, *Tenerife and Its Six Satellites* (1889); L. Diego Cascoy, *The Book of Tenerife* (1957). (R. P. BE.)

**TENGGERESE**, a Proto-Malayan people perhaps with Vedoid strains (see VEDDA), numbering about 10,000 (1960s), and living in the isolated mountain districts of East Java (Republic of Indonesia). Their pagan religious beliefs indicate some influence from the Indo-Javanese and Islamic cultures of the lowlands. They live in small mountainside villages, make clearings in the jungle and raise dry-land rice. See also MALAY ARCHipelago: *Anthropology*.

**TENG HSIAO-P'ING** (c. 1902– ), Chinese revolutionist and a major Communist Party leader, was born in the southwestern Chinese province of Szechwan. After study in France and the Soviet Union in the early and mid-1920s, he returned to China, where he became a leading organizer of Communist guerrilla units in the south. He joined the forces of Mao Tse-tung and Chu Teh in south-central China, fought with them in campaigns against the Nationalists, and participated in the Communist retreat to the northwest known as the Long March (1934–35). During the Sino-Japanese War (1937–45) Teng was a political officer with one of the Communists' major fighting units. In the successful civil war against the Nationalists (1946–49), he continued as a political officer and was among the conquerors of central and southwest China. In the early years of the Communist Chinese regime, established in 1949, Teng served as the party's top official in his native southwest China. He was brought to Peking in 1952 to become a vice-premier, but his major endeavours were within the party organization and by the mid-1950s he was considered one of the half-dozen most powerful men in the nation. He became secretary-general of the party in 1954 (redesignated general secretary in 1956) and a Politburo member in 1955. After the mid-1950s he also was among the leading officials who worked with Communist parties of other countries, specializing in liaison with the party in the Soviet Union. In the 1960s Teng was in the forefront of China's ideological dispute with the Soviet Union; in July 1963 he led a Chinese delegation in Moscow in negotiations that were largely abortive and became a major turning point in the deterioration of Sino-Soviet relations. As a consequence of the "great proletarian cultural revolution" in 1966, Teng seemed to have lost some of his prestige and power in the Communist hierarchy. Nonetheless, he continued, at least nominally, as a major figure in his capacity as general secretary and as head of the party's secretariat. (D. W. KL.)

**TENIERS**, the name of a family of Flemish artists who flourished at Antwerp and Brussels during the 17th century; their most famous member was David Teniers, the younger, prolific painter of genre scenes of peasant life and of paintings of art historical importance showing the collections of the regent of the Netherlands.

DAVID TENIERS, the elder (1582–1649), worked in Antwerp, where he apparently began his career as a pupil of his brother Juliaen; he is also said to have studied in Italy under Elsheimer and Rubens. He became a master in the Antwerp guild in 1606–07, and in the 1630s is recorded as an art dealer. A number of paintings in the style of his more famous son used to be attributed to him, but in fact almost nothing is known about his work except that he seems to have been mainly a painter of religious subjects.

DAVID TENIERS, the younger (1610–1690), the son and pupil of the foregoing, was born in Antwerp, where he was baptized on Dec. 15, 1610, becoming a master in the guild there in 1632–33 and dean in 1645. In 1637 he married Anna, daughter of the painter Jan Brueghel. As an artist he was prolific and painted almost every kind of picture, but chiefly genre scenes of peasant life. His early works in this vein show the influence of Adriaen Brouwer (example in Munich, Bayerische Staatsgemäldesammlungen), but he soon modified the harshness of Brouwer with a blander, sweeter idiom, which he may partly have learned from the Dutch. He was brilliant at handling crowd scenes in an open landscape and adept at characterizing his figures with a warm, human, and often humorous touch. His landscape settings are beautifully atmospheric, and his still-life details attractive and precise. Examples of his work in this manner, the best of which seem to date from the decade 1640–50, are to be found in all the major galleries, since they were extremely popular in the 19th century, especially in England. A typical example is the "Village Fête," signed and dated 1643 (National Gallery, London). In the same decade he also painted a number of monumental processions, such as the "Procession of the Civic Guards of Antwerp" (1643, Leningrad).

Although he continued to paint peasant scenes until nearly the end of his life, latterly with much help from assistants, Teniers developed a second career from 1651 onward, when he became court painter and keeper of the art collections to the regent of the Netherlands, the archduke Leopold Wilhelm, in Brussels. In his capacity as keeper he painted several views of the archduke's picture gallery showing the originals, most of which are now in Vienna, clearly enough for them to be recognized. He also made many small-scale individual copies of these pictures, 244 of which were engraved in 1660 under the title "Theatrum Pictorium." As a pictorial inventory of a great 17th-century collection, this book of engravings was unique in its time and still constitutes an invaluable source for the art historian. Teniers was also court painter to Don John of Austria, who succeeded the archduke as regent in 1656, and was the main founder of the Antwerp Academy, opened in 1665. He died in Brussels on April 25, 1690.

Tenier's son, also named David (1638–1685), often imitated his father's work.

See the excellent short account in H. Gerson and E. H. ter Kuile, *Art and Architecture in Belgium, 1600 to 1800* (1960), pp. 144–47, with further bibliography. (M. W. L. K.)

**TENNANT, FREDERICK ROBERT** (1866–1957), English philosophical theologian who essayed a harmony of science and religion within an empirical approach to theology, was born at Burslem, Staffordshire, on Sept. 1, 1866. He read science at Caius College, Cambridge, and was ordained while teaching science at Newcastle-under-Lyme High School (1891–94), becoming lecturer in theology and fellow of Trinity College, Cambridge, in 1913. He died in Cambridge on Sept. 9, 1957.

In four early books Tennant discussed the concepts of sin (1902, 1912), the fall (1903), and miracle (1925). His articles for the 14th edition of *Encyclopædia Britannica* (1929) included those on "Deism," "Faith," and "Sin." In the first volume (1928) of his chief work, *Philosophical Theology*, he explicitly acknowledges his debt to James Ward (q.v.). In chapter 12 Tennant shows himself temperamentally and philosophically unsympathetic to mysticism and argues that to justify the claims of religious experience to re-

veal God needs an independently established theism, derived by a "laborious ascent" from such knowledge about the self and the world as is supplied by epistemology, psychology, and the natural sciences. Volume ii (1930) describes this ascent and gives Tennant's version of the argument from design: that a broad survey of human life and experience shows the need for the concept of purposiveness in many fields, and such considerations, while inconclusive if taken alone, lead collectively to a cumulative argument for God based on a "cosmic teleology." His bold endeavour to combine scientific and theological thinking was, however, overtaken by developments within both empirical philosophy and theology, where, on different grounds, claims for the reasonableness of Christianity were soon to be condemned. But at a time when religious thought was being challenged more by scientific methods and attitudes than by scientific conclusions, Tennant was a powerful apologist. He brought to his task an acute mind, a wide range of interests, and the ability to develop an argument with a robust thoroughness and notable honesty.

See D. L. Scudder, *Tennant's Philosophical Theology* (1940), with list of his works; and the memoir by C. D. Broad, *Proceedings of the British Academy*, 44:241-252 (1958). (I. T. R.)

**TENNENT**, the name of three prominent American Presbyterian clergymen, father and sons.

**WILLIAM TENNENT** (c. 1673-1745), whose chief contribution to Presbyterianism and to American colonial life was as a teacher of ministers, was born perhaps in the north of Ireland and graduated from the University of Edinburgh in 1695. He began as a Presbyterian but in 1704 and 1706 took orders in the Anglican Church in Ireland. On Sept. 6, 1718, he landed at Philadelphia and ten days later joined the Presbyterian Church. For two years he served in East Chester, N.Y., and several years at Bedford, N.Y., settling later along Neshaminy Creek just north of Philadelphia. There he served as pastor and began in 1736 a small school, called derisively the "Log College." During his career Tennent educated about 21 of the most useful and gifted ministers of the colonial Presbyterian Church, among them his sons Gilbert and William, Samuel Blair, Charles Beatty, John Rodgers, Samuel Finley, and John Redman. They became known as the New Side, opposed to the more rigidly orthodox Old Side of the Scotch-Irish majority. Tennent welcomed the English evangelist George Whitefield (q.v.) to Philadelphia and persuaded him to assist the New Side in its revival effort, known as the Great Awakening. Tennent and the New Side enlisted also the active support of such men as Jonathan Dickinson and Ebenezer Pemberton, thus assuring that colonial Presbyterianism would be predominantly New School. Indirectly, Tennent's Log College was a forerunner of Princeton University, inasmuch as his example inspired the New Side to found Nassau Hall. Tennent died May 6, 1745.

**GILBERT TENNENT** (1703-1764), a popular evangelist second only to Whitefield, and the eldest son of William Tennent, was born in County Armagh, Ire., on Feb. 5, 1703, and educated by his father, with perhaps a year at Yale College. He entered the Presbyterian ministry in Delaware in 1725, and the year after settled at New Brunswick, N.J. Under the influence of his father and of a Dutch pastor, T. J. Frelinghuysen, he soon became a rousing preacher and evangelist. Very quickly he emerged as the natural leader of the "Log College men" and the dominant figure in the Great Awakening. When Whitefield was persuaded by William Tennent to aid the New Side, he found a like spirit in Gilbert, whom he persuaded to follow him up in his evangelistic tour of New England. As a "Sun of Thunder" Tennent did so and became a most controversial figure throughout the colonies. When the Presbyterian Church broke up (1741) into New Side and Old Side, Tennent and Jonathan Dickinson became the two leaders of the New Side. In 1743 Tennent took over Whitefield's tabernacle in Philadelphia and made of it the Second Presbyterian Church. Ten years later he and Samuel Davies raised over £4,000 on a trip through England and Scotland for the building of Nassau Hall. He was a leader in the move that reunited the New Side and the Old Side in 1758. Tennent died July 23, 1764.

**WILLIAM TENNENT** (1705-1777), the second son of the elder William, was born in County Armagh on June 3, 1705. For nearly

44 years he was pastor of the Presbyterian Church at Freehold, N.J. Noted as an eccentric, he was sympathetic with his brother Gilbert's revivalistic views. He died March 8, 1777.

The elder Tennent's younger sons, John and Charles, were also Presbyterian clergymen.

William Tennent* (1807; many later editions), a biography of the younger William but dealing also with other members of the family. (L. J. T.)

**TENNESSEE**, a south-central state of the United States, is bounded on the north by Kentucky and Virginia; on the east by North Carolina along the line of the crest of the Unaka mountains to within 26 mi. (42 km.) of Georgia, where the boundary turns due south; on the south by Georgia, Alabama and Mississippi along the 35th parallel of north latitude; on the west by the Mississippi river, which separates it from Arkansas and Missouri. The extreme length of the state from east to west is 432 mi. (695 km.) and the extreme breadth is 112 mi. (180 km.), its area being 42,244 sq.mi. (109,412 sq.km.) of which 482 are water surface. The name "Volunteer state" was given to Tennessee because of its remarkable record in furnishing volunteers in the War of 1812 and in the Mexican War. It is the 34th state of the union in size. The capital is Nashville and the state entered the union June 1, 1796, as the 16th state. The iris is the state's official flower, the tulip poplar its official tree, and the mockingbird its official bird. The state flag consists of a red field upon the centre of which is depicted a blue circle edged with white and which contains three white five-pointed stars. At the fly end of the flag is a blue stripe separated from the red field by a narrow white stripe. The name "Tennessee," is of Indian origin and is generally believed to be derived from the name of an ancient Cherokee capital.

#### PHYSICAL GEOGRAPHY

**Physical Features.**—The state lies between the extremes of approximately 35° and 36° 41' N. and 81° 40' and 90° 18' W. It is popularly divided into three large divisions known as east, middle and west Tennessee. The first extends from the heights of the Unaka ridges along the North Carolina border, across the valley of the Tennessee river to the heights of the Cumberland plateau. The middle section includes a part of the Cumberland plateau, all the Highland rim plateau and the Central basin, and extends westward to the Tennessee river. The western division includes the plateau region from the Tennessee river to the steep slope which overlooks the Mississippi flood plain; also a narrow strip of lowland which extends to the Mississippi river. From a maximum elevation of 6,642 ft. at Clingmans Dome near the North Carolina border, in Sevier county, the surface descends to 182 ft. on the Mississippi river in Shelby county. The Unaka mountains, which occupy a belt 8 mi. wide along the state's eastern border, are a series of somewhat irregular ridges developed on complexly folded and faulted crystalline rocks. Sixteen peaks exceed 6,000 ft. in height and maximum elevation reaches 6,285 ft. That part of the Great Appalachian valley which traverses Tennessee is known as the valley of east Tennessee. It consists of parallel ridges and valleys developed by erosion on folded sandstones, shales and limestones, the valley quality predominating because the weak limestones were of great thickness. The valley areas vary in height from 600 ft. in the southwest to 1,600 ft. in the northeast. The northeast ridges are more numerous and higher than the southwest.

Along the southwest border of the valley a steep escarpment, known as Walden's ridge, rises to the Cumberland plateau. This plateau has a mean elevation of about 1,800 ft. and a rolling topography, the northern portion sloping toward the northwest.

The western edge of the plateau is much broken by deep indentations of stream valleys, and drops suddenly downward about 1,000 ft. to the Highland rim plateau, so named from the scarp which forms an encircling rim around the Central basin. It is fairly level except where it is cut by river valleys. The Central

basin lies for the most part 400 to 600 ft. below the rim; a few hills or ridges rise to the level of the rim. The basin is elliptical in form, extending nearly across the state from northeast to southwest with an extreme width of about 60 mi.; near its centre is the city of Murfreesboro, and Nashville lies in the northwest.

Between the Central basin and the lower Tennessee river is the western Highland rim. Westward from the lower Tennessee river the surface rises rapidly to the summit of a broken cuesta or ridge and then descends gently and terminates abruptly in a bluff overlooking the Mississippi flood plain. This is called the plateau slope of west Tennessee, which is part of the east Gulf coastal plain. The bluff, 150 to 200 ft. in height, traverses the state in a rather straight course; between it and the meandering Mississippi, except at a few points where that river touches it, lie low bottom lands varying in width according to the bends of the river and containing numerous swamps and ponds. In the northern portion, principally in Lake county, is Reelfoot lake, which occupies a depression formed by an earthquake in 1811. It is 18 mi. long and has a maximum width of 3 mi.

The whole of the Appalachian province of Tennessee and the northern portions of the Cumberland plateau, the Highland rim, and the Central basin are drained southward and westward by the Tennessee river and its tributaries. The valley of the lower Tennessee is drained northward by the same river. The northern portions of the Cumberland plateau, Highland rim and Central basin are drained northward and westward by the Cumberland river and its tributaries. The western slope of the east Gulf plains is drained directly into the Mississippi by several small streams.

**Climate.**—The mean summer temperature varies according to elevation from 62° F. (17° C.) on the Unaka mountains to 72° (22° C.) on the Cumberland plateau, or 75° in the valley of east Tennessee and on the Highland rim, 77° in the Central basin and about 78° on the east Gulf plains of west Tennessee. The mean winter temperature for each of these divisions varies little from 38°, and the mean annual temperature ranges only from 57° in west Tennessee to 58° in middle Tennessee and to 60° in west Tennessee. Killing frosts are rare between the third week in April and the middle of October, especially in the southern and western parts of the state. An average annual precipitation of about 50 in. (1,270 mm.) is quite equally distributed over the state, and a little more than one-half of it is well distributed through the spring and summer months. The average annual snowfall is about 8 in. The

warm, moisture-bearing winds blow low from the south or southwest with a free sweep across the state in a direction nearly parallel with the trend of the mountains. The commingling of these winds with upper cold currents from the north gives rise frequently to westerly and occasionally to easterly winds.

**Soil.**—The Central basin, the less elevated parts of the valley of east Tennessee, and parts of the outer portion of the Highland rim have a fertile soil of limestone origin. There are narrow strips of rich alluvium along many of the rivers. The soils on the mountains, on the ridges of the valley of east Tennessee and on the eastern slope of the east Gulf plains vary greatly, according to the rocks from which they are derived. In the Cumberland plateau, in the inner portion of the Highland rim and in the higher parts of the western slope of the east Gulf plains, the soil for the most part is sandy and thin.

**Plants and Animals.**—At one time the greater part of the state was covered with forests, but less than 10% of the virgin forest remains. There are some great stands of oak, elm and beech that are original growth. Common throughout the state are sycamore, basswood, cherry, walnut, hickory, locust, poplar and maple trees. Hemlock, pine, spruce and balsam are found in abundance in eastern Tennessee. The swampy sections of western Tennessee are similar to the deep south in their vegetation. Cypress, pecan, tupelo, cotton gum and chinquapin grow there. Altogether, more than 150 types of trees are found within the state's borders. Redbud, dogwood, wild grape, passionflower and trailing arbutus are the most widely seen flowering shrubs and vines. Types of wildflowers include violets, daisies, black-eyed Susans, goldenrod, asters, gentians and Jerusalem artichokes. In the mountain regions, the commonest flower is the rhododendron; others frequently seen are many types of trillium, azalea, wild honeysuckle and mountain laurel. The state flower, the iris, is most commonly found in middle Tennessee, as is yellow jasmine. In western Tennessee lilies and orchids abound in the west woodlands.

During pioneer days, bison, elk, Virginia deer, black bears, wolves, panthers and lynxes were common in Tennessee. Virginia deer are still fairly numerous and there are bears and lynxes in the mountainous and wooded parts of the state. Fox, skunks and opossums are probably the best known of the fur-bearing animals found in the state. Others include raccoons, minks, muskrats, rabbits, squirrels, weasels, woodchucks and chipmunks. The Russian wild boar is infrequently seen in the wooded parts of eastern Tennessee. Many birds once common to the region have become extinct there. These include the passenger pigeon, the Carolina parakeet, the ivory-billed woodpecker and the prairie chicken. The bald eagle is found in the wilds of the Cumberland plateau, and on rare occasions golden eagles are seen in the Great Smokies. The great blue heron, the green heron and nearly all of the other types of wading and swimming birds are numerous along the state's waterways. Common birds found include the mockingbird, robin, bluebird, killdeer, meadow lark, cardinal, towhee, screech owl, hawk, chickadee, whippoorwill, flicker, woodpecker and wren. The largest game bird is the wild turkey. Other game birds are grouse, quail, ring-necked pheasant, bobwhite and dove. Of the many kinds of fish found in Tennessee's streams and lakes, particularly numerous are catfish, buffalo fish, drum, bass, pike, jack salmon, crappie, perch and bream. Of the reptiles found in the state, the

rattlesnake, copperhead and cottonmouth moccasin are poisonous.

**State and National Parks, Historic Sites.**—The state parks of Tennessee comprise more than 250,000 ac. (102,000 ha.) of land. Practically all of the parks have lakes and streams and all of them are wildlife refuges. The largest, Natchez Trace State park, is in western Tennessee and contains 42,000 ac. (17,000 ha.). It is named for the famous early road that connected Nashville and Natchez, Miss. Fall Creek Falls State park, (15,777 ac.) contains Fall Creek falls, whose height of 256 ft. make it the highest falls in the eastern United States. David Crockett State park (1,000 ac.) is immediately west of Lawrenceburg, where Crockett lived. Other state parks include Big Ridge, Booker T. Washington, Cedars of Lebanon, Chickasaw, Montgomery Bell, Norris Dam, Pickett, Shelby Forest and Standing Stone. The western half of the Great Smoky Mountains National park is situated on the eastern boundary of Tennessee—the other portion of the park is in North Carolina. The park comprises about 800 sq.mi., with approximately 241,000 ac. in Tennessee. In the park are mountain peaks more than 6,000 ft. in height. Part of the Appalachian trail runs through the park area. Considered one of the most beautiful of the national parks, in part because of the unique, deep blue haze that overhangs the mountains, it was dedicated in 1940.

Meriwether Lewis National monument is in western Tennessee about 35 mi. W. of Columbia, Tenn. Places of historic interest within the monument area include a section of the long-abandoned Natchez trace, and the grave of Meriwether Lewis (q.v.). Fort Donelson National Military park is situated on the site of one of the earliest and most decisive battles of the American Civil War. There Gen. U. S. Grant defeated a Confederate force and captured the fort in 1862. Chickamauga and Chattanooga National Mil-

itary park is partly in Tennessee and partly in Georgia. The Tennessee portion of the park contains the battlefield of Lookout mountain, and Orchard Knob, Missionary Ridge and Signal Point on Signal mountain. The park commemorates two of the most famous military engagements of the Civil War. At Lookout mountain in Nov. 1863 Union forces captured the approaches to Chattanooga and forced a general retreat of the Confederate army into Georgia. Stones River National battlefield near Murfreesboro is located on the site of one of the hardest fought battles of the Civil War. At Stones River the Union army of the Cumberland and the Confederate army of Tennessee fought a three-day battle in Dec. 1862–Jan. 1863. Though both armies suffered heavy casualties, the Union army occupied Murfreesboro and the Confederate army was forced to retreat. Shiloh National Military park commemorates the first major battle of the western campaign during the Civil War. The battle, considered a Confederate defeat, took place in 1862.

## HISTORY

**Exploration and Settlement.**—Eastern Tennessee was recognized as a common hunting ground by the Cherokee, Creeks and other Indian tribes. The Iroquois of New York claimed much of the central portion by right of conquest, and the western section was the home of the Chickasaws.

The first white man known to have visited Tennessee was the Spanish explorer, Hernando de Soto, who in 1540 entered briefly the southeastern portion of the state. Some historians believe De Soto traversed the entire southern portion of the state, crossing the Mississippi river from a point near the present site of Memphis; the generally accepted theory, however, is that he followed a more southerly course through northern Alabama and Mississippi.

Père Marquette, the French missionary and explorer, in his voyage down the Mississippi in 1673, camped upon the western border of the state and eight years later Robert Cavalier, sieur de La Salle, and his companions left Canada to complete the exploration of the river. La Salle built Ft. Prud'homme in 1682 upon a Chickasaw bluff, near the present site of Memphis, but it was soon abandoned. Later the French built Ft. Assumption, where Memphis now stands, and kept a garrison there, but made no attempt at colonization. The territory was a part of the English grant to Sir Walter Raleigh in 1584, and of the later Stuart grants, including that in 1663 to the proprietors of Carolina. James Adair of South Carolina, a fur trader and explorer, is supposed to have been the first to go from the English colonies into Tennessee. A party of Virginians led by Thomas Walker (1715–94) in 1750 reached the Cumberland river and Cumberland mountains and named them in honour of the royal duke. In 1756–57 Ft. Loudoun, named in honour of John Campbell, earl of Loudoun, was built on the Little Tennessee river, about 30 mi. S. of the present site of Knoxville, as an outpost against the French who were then active in the whole

Mississippi valley, and was garrisoned by royal troops. The fort was captured by the Cherokee Indians in 1760, and both the garrison and the neighbouring settlers were massacred.

The first permanent white settler in Tennessee was William Bean, who in 1768 built a cabin along the Watauga river in the northeastern portion of the state. Within the next few years settlements were established near Bean's cabin and also along the Holston and Nolichucky rivers. Hundreds of additional settlers arrived after the defeat of the Regulator insurrection, a popular uprising against excessive taxes, in North Carolina in 1771. These settlers negotiated a ten-year lease with the Cherokees for the land they occupied, and then drew up a compact of government called the Watauga association, mutually binding themselves to observe a body of law. A general committee of 13 was elected to exercise legislative powers and this committee elected 5 of its number to exercise executive and judicial functions. In 1775 the land was purchased from the Cherokees as a part of the negotiations by which Richard Henderson made his famous purchase (see also *KENTUCKY: History*).

**Part of North Carolina.**—With the approach of the American Revolution, the idea of becoming a colony with a royal governor was abandoned, and on petition of the inhabitants the territory was annexed to North Carolina in 1776 as the Washington district, which in 1777 became Washington county, with the Mississippi river as the western boundary. The population increased rapidly and soon several new counties were created.

During the American Revolution the Watauga and Holston settlers joined to defeat decisively the British forces under Maj. Patrick Ferguson. Though warned by Ferguson to cease aiding the Colonial forces, the mountaineers under John Sevier, Isaac Shelby and William Campbell, nevertheless crossed the mountains to attack Ferguson on Oct. 7, 1780, caught up with him at King's mountain, S.C., and aided by some North Carolina troops, killed or captured his entire force. In 1779 James Robertson (1742–1814) led an overland expedition that planted a settlement on the Cumberland river in middle Tennessee. The women and children of Robertson's party arrived at the settlement in the spring of 1780 after a harrowing four-month voyage down the Tennessee river and then up the Ohio and Cumberland rivers, under the command of John Donelson. The infant settlement of Nashville, named after Gen. Francis Nash of North Carolina, was self-governed after the fashion of its sister settlement in east Tennessee. The Cumberland compact, which contained the first provision for recall of elected officials in the history of the United States, remained in force until 1783, when North Carolina made the renamed town of Nashville the county seat of the newly created Davidson county.

**The State of Franklin.**—After the American Revolution the legislature of North Carolina offered in 1784 to cede its western territory to the general government, provided the cession be accepted within two years. The Watauga settlers, indignant at this transfer without their consent, and fearing to be left without any form of government whatever, assembled in convention at Jonesboro on Aug. 23, 1784, and chose delegates to a later convention to form a new state. Meanwhile North Carolina repealed the act of cession and created the western counties into a new judicial district. A second convention of the Watauga settlers broke up in confusion without accomplishing anything; but a third adopted a constitution, which was submitted to the people, and ordered the election of a legislature. This body met early in 1785, elected Sevier governor of the new state of Franklin, filled a number of offices and passed several laws in anticipation of an autonomous existence.

In May 1785 William Cocke presented to the federal congress a memorial requesting recognition of Franklin as a state. Congress refused to accede to this request, however, and subsequently North Carolina renewed its efforts to effect a return of the "Franklinites" to the allegiance of the mother state. For a time two sets of officials claimed authority in Franklin; but North Carolina finally prevailed after remitting taxes unpaid since 1784. In 1788 Sevier's term as governor of Franklin expired, and, no successor being elected, the state of Franklin came to an end. Sevier was

arrested on a charge of treason, but was allowed to escape, and soon afterward was again appointed brigadier general of militia.

**The State of Tennessee.**—On Dec. 12, 1789, North Carolina again ceded the territory to the United States government, stipulating that all the general provisions of the ordinance of 1787 should apply except that forbidding slavery. Congress accepted the cession and, on May 26, 1790, passed an act for the government of the "Territory south of the River Ohio." William Blount was appointed the first governor, and in 1792 Knoxville became the seat of government. The chief events of Blount's administration were the contests with the Indians, the purchase of their lands and the struggle against Spanish influence.

A census ordered by the territorial legislature in 1795 showed more than 60,000 free inhabitants (the number prescribed before the territory could become a state), and accordingly a convention to draft a state constitution met in Knoxville on Jan. 11, 1796. The instrument, which closely followed the constitution of North Carolina, was proclaimed without submission to popular vote. Sevier was elected governor, and Blount and Cocke United States senators. In spite of the opposition of the Federalist party the state of Tennessee was admitted to the union on June 1, 1796.

With the subsequent rapid increase of population, the dread of Indians and Spaniards declined. Churches and schools were built, and soon many of the comforts and some of the luxuries of life made their appearance. The question of a circulating medium of exchange was acute during the first half of the 19th century, and state banks were organized, but they suspended specie payments in times of financial stringency. The bank of Tennessee, organized in 1838, had behind it the credit of the state, and it was hoped that money for education and for internal improvements might be secured from its profits. The management became a question of party politics, and later, during the American Civil War, its funds were used to advance the Confederate cause.

The development of west Tennessee along the Mississippi was rapid after the beginning of the 19th century. This section was purchased from the Chickasaw Indians in 1818, and in the following year Tennessee's most populous county, Shelby, was created with its county seat at Chickasaw Bluffs (now Memphis).

The peculiar topographical conditions made the three sections of the state almost separate commonwealths, and demand for better means of communication was insistent. The policy of state aid to internal improvements found advocates very early, but a definite program was not begun until 1829 when commissioners for internal improvements were appointed and an expenditure of \$150,000 was authorized. In 1835 the state agreed to subscribe one-third to the capital stock of companies organized to lay out turnpikes, railways, etc., and four years later the proportion became one-half. The general policy was continued, and in 1861 more than \$17,000,000 of the state debt was due to these subscriptions, from which there was little return.

Andrew Jackson was the dominant figure in Tennessee politics during the second quarter of the 19th century. The state's first representative in congress and one of its first superior court judges, Jackson's career had gone into virtual eclipse until his well-earned fame in the War of 1812 revived it. His nomination for president in 1824 ushered in a period during which he literally dictated his party's policies, but his attempt to dictate the election of Martin Van Buren as his successor in 1836 brought about a revolt against him in his own state. Sen. Hugh Lawson White received Tennessee's electoral votes that year and his followers became the leaders of the newly formed Whig party. During the next 20 years that party carried every presidential election in Tennessee, including even that of 1844 when a native son, James K. Polk, was the Democratic candidate for president.

**The American Civil War.**—When the Whig party split nationally on the slavery issue Tennessee became nominally Democratic. Proslavery sentiment was strong in middle and west Tennessee, but less strong in east Tennessee; loyalty to the Union, however, was strong in all sections of the state. The lack of a strong secessionist sentiment among the people of the state helped prevent the adoption of extreme measures when the representatives of nine southern states met in Nashville in 1850 to consider

the sectional issues confronting the country. In 1860 Tennesseans again demonstrated their loyalty by voting for the Constitutional Union party's candidates, John Bell and Edward Everett, in the presidential elections. As late as Feb. 9, 1861, voters defeated a proposal to hold a convention for the consideration of seceding from the Union.

This pro-Union sentiment changed almost overnight when Pres. Abraham Lincoln called on Tennessee to provide troops to help put down the southern rebellion. On May 7, 1861, the state entered into a "military league" with the Confederacy, and on June 8 the people of middle and west Tennessee voted overwhelmingly to sever their ties with the Union; by an equally overwhelming majority east Tennessee voted to remain in the Union. Thus, when Gov. Isham G. Harris proclaimed that Tennessee had declared its independence of the union, Andrew Johnson of east Tennessee refused to resign his seat in the United States senate and was upheld in that action by the people of his section. East Tennessee remained Unionist throughout the Civil War, and has been strongly Republican in its politics ever since.

Next to Virginia, the state was the chief battleground during the Civil War. In Feb. 1862 Gen. U. S. Grant and Commodore A. H. Foote captured Ft. Henry on the Tennessee river and Ft. Donelson on the Cumberland. The Confederate line of defense was broken and Gen. D. C. Buell occupied Nashville. Grant next ascended the Tennessee river to Pittsburg Landing, with the intention of capturing the Memphis and Charleston railway, and on April 6 and 7 defeated the Confederates in the battle of Shiloh. The capture of Island No. 10 in the Mississippi on April 7 opened the river as far south as Memphis, which was captured in June. During Dec. 31-Jan. 2 Gen. William S. Rosecrans (Federal) fought with Gen. Braxton Bragg (Confederate) the bloody but indecisive battle of Stone River (Murfreesboro). In June 1863 Rosecrans forced Bragg to evacuate Chattanooga. Bragg, however, turned upon his pursuer, and on Sept. 19 and 20 in one of the bloodiest battles of the war, defeated Rosecrans at Chickamauga. General Grant then assumed command, and on Nov. 24-25 defeated Bragg at Chattanooga, thus opening the way into east Tennessee. There Confederate Gen. A. E. Burnside at first met with success, but was shut up in Knoxville by Gen. James Longstreet, who was not able, however, to capture the city, and on the approach of Gen. W. T. Sherman retired into Virginia. Almost the whole state was now held by Federal troops, and no considerable military movement occurred until after the fall of Atlanta in Sept. 1864. Then Gen. J. B. Hood moved into Tennessee, expecting Sherman to follow him. Sherman, however, sent reinforcements to Thomas and continued his march to the sea. Hood fought with Gen. John M. Schofield at Franklin, and on Dec. 15-16 was utterly defeated by Gen. George H. Thomas at Nashville, the Federals thus securing virtually undisputed control of the state. (See AMERICAN CIVIL WAR).

**Reconstruction.**—After the occupation of the state by the Federal armies in 1862, Andrew Johnson was appointed military governor by the president (confirmed March 3, 1862), and held the office until he was inaugurated vice-president of the U.S. on March 4, 1865. Republican electors attempted to cast the vote of the state in the national election of 1864, but were not recognized by congress.

Tennessee was the first of the Confederate states to be readmitted to the union (July 24, 1866) after ratifying the 13th and 14th amendments to the United States constitution. Tennessee freed its slaves by an amendment to the state constitution ratified by a vote of the people on Feb. 22, 1865, but suffrage was not conferred upon the Negro until two years later (Feb. 25, 1867). The state escaped "carpet bag" government, but the native whites in control, under the leadership of William G. Brownlow, exhibited almost every phase of the Reconstruction policy. All persons who had either directly or indirectly taken part in the war against the union or had given aid to the Confederacy were denied the right of suffrage. In the election of 1869, the acting governor, D. W. C. Senter, ordered the election commissioners to issue to all actual citizens of the state permits to vote. The Democrats united with the conservative Republicans and Senter was easily elected. At

the same time a Democratic and conservative legislature was elected, thus placing the state government again in the control of officers elected by the majority of the people. The Ku Klux Klan, originating in 1865 at Pulaski, Tenn., spread over the state and the entire south, and in 1869 nine counties in the middle and western section were placed under martial law because of the Klan's activities against the Loyal (or Union) league, an organization supporting the union, and the Negroes.

A constitutional convention, which met in Jan. 1870, revised the old constitution, and the revision became the state constitution when ratified by the people the following May. In 1873 a school law was passed which provided for state and county superintendents and separate schools for white and Negro children and levied a state tax to aid in paying the expenses of these schools. A progressive step was the final compounding of the old state debt at 50 cents on the dollar by an act of the legislature in 1883.

In 1904 the Adams law, which prohibited the sale of intoxicating liquors in towns of 5,000 inhabitants or less, was passed. Successive laws concerning prohibition were passed in 1910, 1913, 1915 and 1917; nevertheless, Tennessee voted for repeal of national prohibition in 1933. In 1915 a law was passed providing for mothers' pensions. In 1917 the letting of prison labour to private contractors was prohibited, and an act was passed forbidding the limiting of the output of coal in order to increase the price. In the same year a state budget commission was created. On Aug. 18, 1920, the state ratified the proposed amendment to the federal constitution, providing for woman suffrage. As the 36th state to ratify, Tennessee brought the number to the requisite three-fourths.

After World War I Tennessee became a major industrial state, largely as a result of the Tennessee Valley authority (TVA). This giant network of navigation-flood control-hydroelectric power dams on the Tennessee river and its tributaries began with the construction of Wilson dam at Muscle Shoals, Ala., in 1916. This dam, intended originally for the production of nitrates and left unfinished at the end of the war, became the focus of the controversy in the 1920s between private power interests and those who advocated governmental development of the hydroelectric potential of the Tennessee river. The dedication of Sen. George W. Norris of Nebraska to the development of public power facilities which could be used as a "yardstick" against which to measure the rates of private power companies reached fruition in 1933 when the TVA was created as a part of Pres. Franklin D. Roosevelt's New Deal program. The subsequent building of dams which provided cheap electric power to the area, and the later development of giant steam plants which provided additional power both for industry and for atomic power installations in Tennessee and Kentucky did much to improve Tennessee's economy.

**Modern Politics and Issues.**—Except for the years 1881-83, 1911-15 and 1921-23, the Democratic party has controlled the executive office since 1870. In 1920 and again in 1928 the state gave its electoral votes to the Republican presidential candidate. Tennessee returned to the Democratic fold in 1932, but in 1952, 1956 (despite the fact that in that year Tennessean Estes Kefauver was the Democratic nominee for vice-president) and 1960 the Republican party won the state's electoral votes. Tennessee remained firmly Democratic in state elections and in the election of senators, and of representatives in all but the two east Tennessee congressional districts. The Democratic presidential candidate Lyndon B. Johnson, carried Tennessee in the 1964 election. The first Republican elected to the U.S. senate from Tennessee by popular vote was Howard H. Baker, Jr., in 1966.

## GOVERNMENT

Tennessee's constitution has been amended only once (in 1953) since its adoption in 1870. The constitution's cumbersome amending process, though somewhat liberalized at that time, still requires that a proposed amendment pass both houses of two consecutive general assemblies, the first time by a majority of the total membership of each house and the second time by a two-thirds vote of the total membership, after which it must be ratified by a majority of all citizens of the state voting in the gubernatorial election. Amendments may also be proposed by a

constitutional convention and ratified in like manner by the people, but the legislature must first propose the holding of such a convention and this proposal must be approved by a majority of those who vote on it at a governor's election. Other changes made included the lengthening of the governor's term of office from two to four years with the provision that he could not succeed himself; the granting to the governor of the power of veto over individual items in appropriations bills; the consolidation of certain city and county functions; the raising of legislator's salaries; the granting of a certain amount of home rule to localities; and the repeal of the poll tax, which, in fact, had not been regularly collected.

State elections are held in even-numbered years on the first Tuesday after the first Monday in November, but local and county elections are held the first Thursday of August, which, in even-numbered years, is also the date for statewide primary elections.

**Legislative.**—The governor is the state's only popularly elected executive officer. He is elected for a term of four years and is not eligible to succeed himself. The speaker of the state senate is, by virtue of that office, lieutenant governor and succeeds the governor in the event of his death or removal from office. The treasurer, comptroller of the treasury and secretary of state are elected by joint ballot of both houses of the general assembly. The secretary of state's term is four years; the others are two-year terms. The attorney general is appointed by the members of the supreme court for an eight-year term. The heads of the major departments of the state government are appointed by and serve at the pleasure of the governor. These departments are agriculture, conservation, corrections, education, employment security, finance and taxation, highways and public works, insurance and banking, labour, mental health, public health, public welfare and safety.

Following the historic U.S. supreme court decision in *Baker v. Carr* on March 26, 1962, that Tennessee's legislative apportionment was a proper subject for review by federal courts, a special session of the legislature adopted reapportionment legislation for the first time since 1901; this gave greater representation to urban areas but was found by a federal court still to be inadequate. The court set a 1966 deadline for the legislature to remedy the inequity. State senators and representatives are elected for two-year terms. The number of representatives is limited by the constitution to 99; there are 33 senators. The legislature meets biennially, in odd-numbered years for a maximum of 75 days in regular session and 20 days in an extraordinary session called by the governor. Bills may originate in either house, but no bill can become law unless it receives a majority vote of the full membership of each house. A veto by the governor can be overridden by the same majority vote. No minister, priest or rabbi is eligible for membership in the legislature.

**Judiciary.**—The administration of justice is vested in a supreme court, a court of appeals, chancery courts, circuit courts, criminal courts, courts of general sessions, county courts, justice of the peace courts and recorders' courts. The supreme court, which has appellate jurisdiction only, consists of five judges elected by the state at large for a term of eight years, one for each of the three grand divisions (east, middle and west) and two for the state at large. The judges designate one of their number to preside as chief justice. The court of appeals is composed of nine judges, three from each grand division of the state, elected for a term of eight years. This court has jurisdiction of appeals in all equity cases, with a few exceptions, and it may transfer any case to the supreme court. The state is divided into 15 chancery divisions. Chancellors are elected for terms of eight years, and a court of chancery is held in every county seat in each division. Many of the divisions have more than one chancellor.

The state is divided into 21 circuits, in each of which a circuit judge is elected for a term of eight years, and a circuit is held in every county seat. Some circuits have more than one judge. There are also 15 criminal judges, principally in the most heavily populated areas, who are elected for eight-year terms.

Each county is divided into civil districts, varying in number according to population or other factors, and each district elects

at least two justices of the peace for a term of six years; each county town or incorporated town also elects one justice of the peace. A recorder has concurrent jurisdiction with a justice of the peace. In several of the counties the county court is composed of a county judge, elected for a term of eight years, together with the justices of the peace. In other counties the court is composed of the justices of the peace alone who elect one of their number as chairman. The government of each county is vested principally in the county court. A county trustee, whose duty it is to collect state and county taxes, and a sheriff are elected by the people of the county for a term of two years; a clerk of the county court and a registrar are also elected by the voters of the county for a term of four years.

**Finance.**—Educational appropriations consume the largest portion of the total expenditure of state funds, with highways second and public welfare third. Chief sources of revenue are general sales tax, motor vehicle licences, general property tax, gasoline tax, tax on insurance companies, sales tax on tobacco and alcoholic beverages, an excise tax and an inheritance tax. Various other licences, fines and forfeitures help to augment the state's revenue funds.

Total state revenues in the second half of the 20th century were nearly \$400,000,000 annually; total expenditures were about \$375,000,000 of which about 29% was for education, nearly 24% was for highways, nearly 14% for welfare and more than 10% for cities and local governments. The gross debt was about \$115,000,000. Though personal income was up considerably since World War II, the state's per capita income remained among the lowest in the nation.

## POPULATION

The population of Tennessee in 1800, four years after it obtained statehood, was 105,602. Its population ranked 15th among the 22 states and territories that then composed the union, and was classified as 100% rural. The period from the first census in 1790 to 1800 was the one of the most rapid growth in the state's history—the population increased by nearly 196% during that time. Immediately before the Civil War, in 1860, the state had a population of 1,258,520 of whom about 275,000 were Negro slaves. It had advanced to the 8th most populous state, and was about 96% rural in character. At the beginning of the 20th century, the state had slipped to 14th in rank of population with a total of 2,020,616 persons by the 1900 census. It was still largely rural in character: about 84% of the people were classified as nonurban dwellers. The decade between 1910 and 1920 was the period of the slowest growth in the state's history. In 1920 the population was only 7% greater than it had been in 1910. Since 1920 the Negro population has been steadily rising, but its proportion of the total population has been declining since 1880. The 1950 population showed a total of 3,291,718 persons living within the state, making Tennessee the 16th in size of population among the states. The rural population had declined to 55.9% of the total at that time. There were four standard metropolitan areas in 1960. They were Chattanooga (Hamilton County in Tennessee and Walker County in Georgia); Knoxville (Anderson, Blount and Knox counties); Memphis (Shelby County in Tennessee, to which Crittenden County in Arkansas was added in 1963); and Nashville (Davidson County to which Sumner and Wilson counties were added in 1963). In 1960, 47.6% of the state's population lived in these metropolitan areas.

In 1960 Tennessee had a population of 3,567,089, an increase of 275,371 or 8.4% over 1950. The state ranked 17th in size of population. The population per square mile in 1960 was 84.4 (326.0 per square kilometer), as compared with 49.6 for the U.S. as a whole. The 1960 urban population was 1,864,828 or 52.3% of the total, continuing the trend toward increasing urban residence. Distribution by race and nativity, according to the 1960 census was as follows: 83.5% native white; 0.4% foreign-born white and 16.5% nonwhite, practically all Negro. In line with the rest of the U.S. the percentage of persons 65 years old or over was increasing, being 8.7% in 1960. The percentage of the population 14 years old and over that was in the labour force was 52.6 in 1960.

Note: Dash indicates place did not exist during reported census, or data not available.

## EDUCATION

The first steps toward the creation of a common school system for Tennessee were taken in 1823, when an act was passed setting aside for school purposes the revenue and taxes accruing from public lands. From that beginning until the adoption of a uniform school code in 1925, more than 1,000 different acts were passed pertaining to the educational system.

Under the new code the administration is vested in a state commissioner of education; a state board of education, consisting of the commissioner, the governor and nine other members; a county superintendent and a county board in each county; and in cities, city boards of education.

The commissioner and the other members of the state board are appointed by the governor. The county superintendent is elected biennially by either the county court or by popular ballot. The county board consists of seven members (unless otherwise provided), elected by the county court or by popular ballot, for a term of seven years, one retiring annually.

The state board of education prescribes the rules and regulations for the operation of the school program, and prescribes standards and requirements for curriculum, teacher certification, school buildings, grading and instructional materials. It also maintains and controls the five state colleges and Tennessee Agricultural and Industrial state university.

The quarterly county court has power to issue bonds, levy taxes and provide funds for buildings for the county schools. The court is under obligation to maintain at least one four-year high school within the county.

Public schools are free to all persons above six years of age.

Attendance is compulsory between the ages of 7 and 16 unless high school standing has been attained. A state that had a history of segregated schools for whites and Negroes, Tennessee began to desegregate them after the U.S. supreme court decision in 1954 declared such schools unconstitutional.

**Universities and Colleges.**—The largest institution of higher learning provided by the state is the University of Tennessee, at Knoxville. Chartered by the legislature of the Southwest Territory in 1794 under the name of Blount college, it became East Tennessee college in 1807 and East Tennessee university in 1840. It was incorporated as Agricultural and Mechanical college in 1869 and took its present name in 1879. The main campus remains at Knoxville, but the graduate school; school of biological sciences; colleges of medicine, dentistry and pharmacy; school of nursing; and division of public health are at Memphis. The agricultural extension branch office and the school of social work are at Nashville; substations of the agricultural experiment station are at Jackson, Columbia, Greeneville, Crossville, Springfield and Lewisburg; and there is a branch of the university at Martin. Other state-controlled schools include Memphis State university (1909); East Tennessee State university at Johnson City (1911); Middle Tennessee State college at Murfreesboro (1909); Tennessee Polytechnic institute at Cookeville (1915); Austin Peay State college at Clarksville (1927); and Tennessee Agricultural and Industrial State university at Nashville (1912).

Privately controlled institutions of higher learning include Belmont college, Nashville (Baptist, 1951); Bethel college, McKenzie (Presbyterian, 1842); Carson-Newman college, Jefferson City (Baptist, 1851); Christian Brothers college, Memphis (Roman Catholic, 1871); David Lipscomb college, Nashville (Church of Christ, 1891); Fisk university, Nashville (American Missionary association affiliate, 1867), originally established by the Freedmen's bureau as a school for Negroes; George Peabody College for Teachers, Nashville (nonsectarian, 1785); King college, Bristol (Presbyterian, 1867); Knoxville college, Knoxville (United Presbyterian, 1875) for Negroes; Lambuth college, Jackson (Methodist, 1923); Lane college, Jackson (Methodist Episcopal, 1832) for Negroes; Le Moyne college, Memphis (Congregational Christian, 1871) for Negroes; Lincoln Memorial university, Harrogate (nonsectarian, 1897); Maryville college, Maryville (United Presbyterian, 1819); Scarritt College for Christian Workers, Nashville (Methodist, 1892); Siena college, Memphis (Roman Catholic, 1922); Southern Missionary college, Collegedale (Seventh-day Adventist, 1893); Southwestern at Memphis, Memphis (Presbyterian, 1848); Tennessee Wesleyan college, Athens (Methodist, 1857); Tusculum college, Greeneville (United Presbyterian, 1794); Union university, Jackson (Baptist, 1825); University of Chattanooga, Chattanooga (nonsectarian, 1886); University of the South, Sewanee (Protestant Episcopal, 1857); and Vanderbilt university, Nashville (nonsectarian, 1873), one of the best-known schools in the south and endowed by Cornelius Vanderbilt.

## HEALTH, WELFARE AND CORRECTIONS

The state department of public health, headed by a commissioner of cabinet rank, is made up of 11 divisions which have jurisdiction over central administration, local health service, crippled children's service, dental health, laboratories, preventable diseases, sanitary engineering, tuberculosis control, vital statistics, hospital department of mental health provides psychological, nursing, statistical, fiscal and personnel service, as well as directing work in forensic psychiatry, mental health education, psychiatric social work, nutrition and the engineering and planning of mental health installations. There are state mental hospitals at Knoxville, Nashville and Bolivar; a psychiatric hospital in Memphis; a home for the mentally defective in Donelson; and community mental health centres in various parts of the state.

The department of correction has its main penitentiary at Nashville. A branch known as Brushy Mountain prison, is located at Petros in east Tennessee. There the prisoners work principally in the state coal mines and on a farm. Fort Pillow state farm in west Tennessee is primarily for first offenders.

The department of public welfare administers programs of public assistance to the aged, the blind, the disabled and to dependent children. It also aids in rehabilitation and training of sightless persons; regulates public and private child care agencies; oversees adoptions and placing of dependent children in foster homes.

### THE ECONOMY

Tennessee was primarily an agricultural state until the second quarter of the 20th century, when manufacturing became the major source of the state's wealth. Pre-Civil War Tennessee, especially the middle and western portions, belonged to that complex of southern states in which cotton was "king"; however, the state's economy was never as completely geared to cotton as that of the states of the deep south. Tobacco has almost always been the second most valuable crop in the state, with corn, hay and wheat also ranking high in value of production. Since World War II Tennessee's already diversified farming has been affected by two significant trends: a greater emphasis on livestock production and the mechanization of farm operations. The breeding of show cattle, particularly of the Jersey, Angus and Hereford breeds, has become important in the state's rapidly growing livestock and dairy industry. Tennessee walking horses are bred almost solely for show. The once comfortable and utilitarian plantation horse with its "rocking chair ride" became less a riding horse, though its exaggerated gaits are much admired in some show circles.

**Agriculture.**—The number of acres of farmland remained fairly constant in the second half of the 20th century, but with more intensive cultivation there had been a constant decline in acres of cropland harvested. By the 1960s there were about 1,400,000 ac. less than in 1925. Much former cropland had been turned into pasture needed for the growing livestock industry in Tennessee. During this same period the size of the average farm increased from 70.8 to about 87 ac. and the average value of land and buildings from about \$3,000 to about \$7,500. The number of farm operators declined from more than 250,000 to slightly more than 200,000, of whom approximately 120,000 were full owners, 30,000 part owners and 50,000 tenants; there were about 400 managers. Of the farm operators about 10% were nonwhites, most of them Negroes. Tennessee farmers averaged total cash receipts from farming of more than \$475,000,000 annually, about evenly divided between livestock and livestock products and crops. Leading income producers in the livestock category were dairy products, cattle and hogs. Leading crops were corn, hay, tobacco, wheat and cotton.

**Forests.**—In the 1960s Tennessee's forest lands totaled 12,408,000 ac. and contributed a large portion of the state's agricultural and industrial income through lumber and wood products, furniture and pulp paper industries.

**Minerals.**—Tennessee ranks about 27th among the states in the value of its mineral products. The principal minerals are coal, cement, stone, phosphate rock, zinc and copper. Other mineral products of economic value were clays, lime, manganese, sand and gravel, lead, gold, silver, barite, petroleum, natural gas and celestite. Tennessee produces most of the copper mined in the southern states; this metal, with the gold and silver by-products of the smelting process, is largely confined to Polk county in the southeastern portion of the state. The coal-producing area is in the Cumberland plateau; building marble, for which Tennessee is famous, comes from the eastern part of the state; and phosphate deposits are localized in middle Tennessee.

**Manufacturing.**—Tennessee experienced a rapid industrial development in the second half of the 20th century. From the early 1930s to the 1960s the number of manufacturing establishments and their employees approximately tripled. Chief industries were chemicals, food and kindred products, textiles, apparel, lumber and wood products, pulp and paper, furniture and fixtures, printing and publishing, primary metals, fabricated metals, leather and leather products. Among the biggest industrial installations were the giant aluminum plant at Alcoa, chemical plants at Kingsport and Old Hickory and newsprint mills at Calhoun.

**Transportation.**—Railway mileage in Tennessee, 4,078 mi. in 1920, had decreased to less than 3,500 mi. by the 1960s. Parallel-

ing the decline of railway mileage was a steady growth of the highway system which totaled more than 70,000 mi. by the 1960s, of which about 8,000 mi. were state roads and the remainder county. Much freight formerly handled by railroads had been taken over by highway trucking firms; much additional freight was being carried by boats on the Tennessee and Cumberland rivers, where huge dams and locks constructed by the Tennessee Valley authority and by the U.S. army corps of engineers had made possible massive barge tows and extremely low shipping charges.

Current statistics on production, employment, industry, etc., may be obtained from the pertinent state departments; the principal figures are summarized annually in the *Britannica Book of the Year*. (W. T. A.)

**TENNESSEE RIVER**, the largest tributary of the Ohio river, U.S. It is formed by the confluence of the Holston and the French Broad rivers 4.5 mi. (7.2 km.) above Knoxville, Tenn. The upstream tributaries of the Tennessee drain the southern portion of the Appalachian mountains, and the highest part, known as the Great Smokies, receives the largest total rainfall in the eastern half of the U.S. The Holston, the Clinch and their tributaries rise on the mountain slopes that flank the valleys in western Virginia; the French Broad and the Little Tennessee and their tributaries rise in the high mountains of western North Carolina; the Hiwassee and its tributaries rise in the mountains of western North Carolina and northern Georgia.

The Tennessee flows south-southwest to Chattanooga, there turns west through the Cumberland plateau and into the northeast corner of Alabama, continues west across the northern part of Alabama, turns north on the boundary between Alabama and Mississippi and, continuing north across Tennessee and Kentucky, unites with the Ohio at Paducah, Ky. The drainage basin includes parts of seven states.

The Tennessee itself is 652 mi. (1,049 km.) long, and with the Holston and the North fork of the Holston forms a channel about 900 mi. (1,450 km.) long. Its drainage basin covers about 39,000 sq.mi. (99,800 sq.km.).

**History.**—The name of the river, like that of the state, may have come from a village of the Cherokee Indians, located on the Little Tennessee near its mouth, and named "Tanase" or "Tennessee."

Detailed exploration of the Tennessee river took place during the period of rivalry between the French and the English for the territory west of the Appalachians. A few small forts and posts had been established by each rival. Previous to this, other early

explorers and fur traders had entered the lower river from the Ohio.

The lands along the upper (Holston and Watauga) valley began to receive American settlers by the 1770s and 1780s. These had crossed the Appalachians from North Carolina or had arrived by way of the Appalachian valley routes (such as the Shenandoah) from Virginia and Pennsylvania. The first house in Knoxville, at the head of the Tennessee, was built in 1786; the townsite was soon surveyed. By this time it became possible for the river itself to serve as a route for further movement southwestward. Many settlers continued downstream on flatboats to the lands between Knoxville and Chattanooga, or into what is now northern Alabama. However, more westward settlements resulted from travel on overland routes through the Cumberland gap (60 mi. northeast of Knoxville) or on roads westward across the Cumberlandlands. The role of the Tennessee as a westward passage was negligible as compared to the Ohio.

Originally the Tennessee was navigated with difficulty, and only by shallow-draft boats. The upper course was shallow where mountain ridges were breached, filled with short rapids which hindered navigation except at high water and the river was subject to seasonal fluctuations. The rapid run-off from mountainous upstream tributaries, followed by periods of lower flow, resulted in both downstream floods and periods of insufficient water for safe navigation. The middle course of the Tennessee, through the Cumberlandlands, was tortuous, contained whirlpools and was interrupted by the famous Muscle Shoals (*q.v.*). Only the lower course, north-flowing in western Tennessee, was easily navigated.

The Tennessee furnished an early but circuitous route to eastern markets for flour, bacon, whisky and other products of the pioneers. Flatboats made the downstream journey to the Ohio, and thence to the Mississippi and to New Orleans. From there shipments went by sea to Atlantic coast markets. Upstream traffic, via keelboats, was not important. Steamboat operation on the river dates mainly from the 1820s. The advent of railroads in the valley, after the 1840s, kept river traffic from assuming the significance it had on other western, more easily navigated rivers.

Only two cities of considerable size are on the Tennessee: Knoxville at the head of navigation, and Chattanooga at an important river crossing and route centre. Traffic westward from Chattanooga focuses through the "gorge" of the river, cut through the Cumberland plateau. In early settlement days the site of Chattanooga was an important "landing." Cities of moderate size on the river (all in Alabama) are Guntersville, Decatur, Florence and Tusculumbia; these date from early settlement. Sheffield, also on the river, was not founded until the 1880s. Savannah, in western Tennessee, is the largest town on the lower course. Many of the early "landings" and "ferries" were by the second half of the 20th century only hamlets or were in ruins.

The northward-flowing lower course of the Tennessee was of utmost importance during the Civil War. It and its valley offered an invasion route into the western Confederacy. The very downstream part of the course is paralleled by the Cumberland river (*q.v.*). Confederate Ft. Henry was on the Tennessee; Ft. Donelson was 12 mi. away on the Cumberland. The army of General Grant, accompanied by federal gunboats, struck southward in the valley in February 1862. The Confederate armies fell back to Corinth, Miss., and the Union armies moved almost to the southern boundary of Tennessee. Here was fought the battle called either Pittsburgh Landing or Shiloh. With the eventual capture of the middle and western valley by Union forces, and the fall of Chattanooga, the entire Tennessee valley fell to Union forces. The upper valley in mountainous east Tennessee saw little fighting except at Knoxville; in fact, many upper east Tennesseans remained loyal to the Union.

River traffic on the Tennessee remained of only moderate importance into the early 1900s. Interestingly, for a time, marble from the Knoxville and other quarries was actually shipped to eastern building projects via the circuitous river route. The development of the river system to a higher place among the inland waterways of the United States came during the 20th century (see TENNESSEE VALLEY AUTHORITY).

The Tennessee is today a series of reservoirs, called lakes, each impounded by a dam. The nine mainstream dams are Kentucky, in Kentucky; Pickwick Landing, in Tennessee; Wilson, Wheeler and Guntersville, in Alabama; and Hales Bar, Chickamauga, Watts Bar, and Ft. Loudoun (which impounds the water to Knoxville at the confluence of Holston and French Broad), in Tennessee. The impoundments are extensively used for recreation. (L. Do.)

**TENNESSEE VALLEY AUTHORITY**, a U.S. government agency established in 1933 to control floods, improve navigation and produce electrical power along the Tennessee river and its tributaries. The jurisdiction of the Tennessee Valley authority (TVA) is generally limited to the drainage basin of the Tennessee river, but some of its activities extend beyond the region.

The drainage basin, an area of almost 39,000 sq. mi. (99,800 sq. km.) covers parts of seven states. Alabama, Georgia, Kentucky, Mississippi, North Carolina, Tennessee and Virginia. Its 1965 population was approximately 3,500,000.

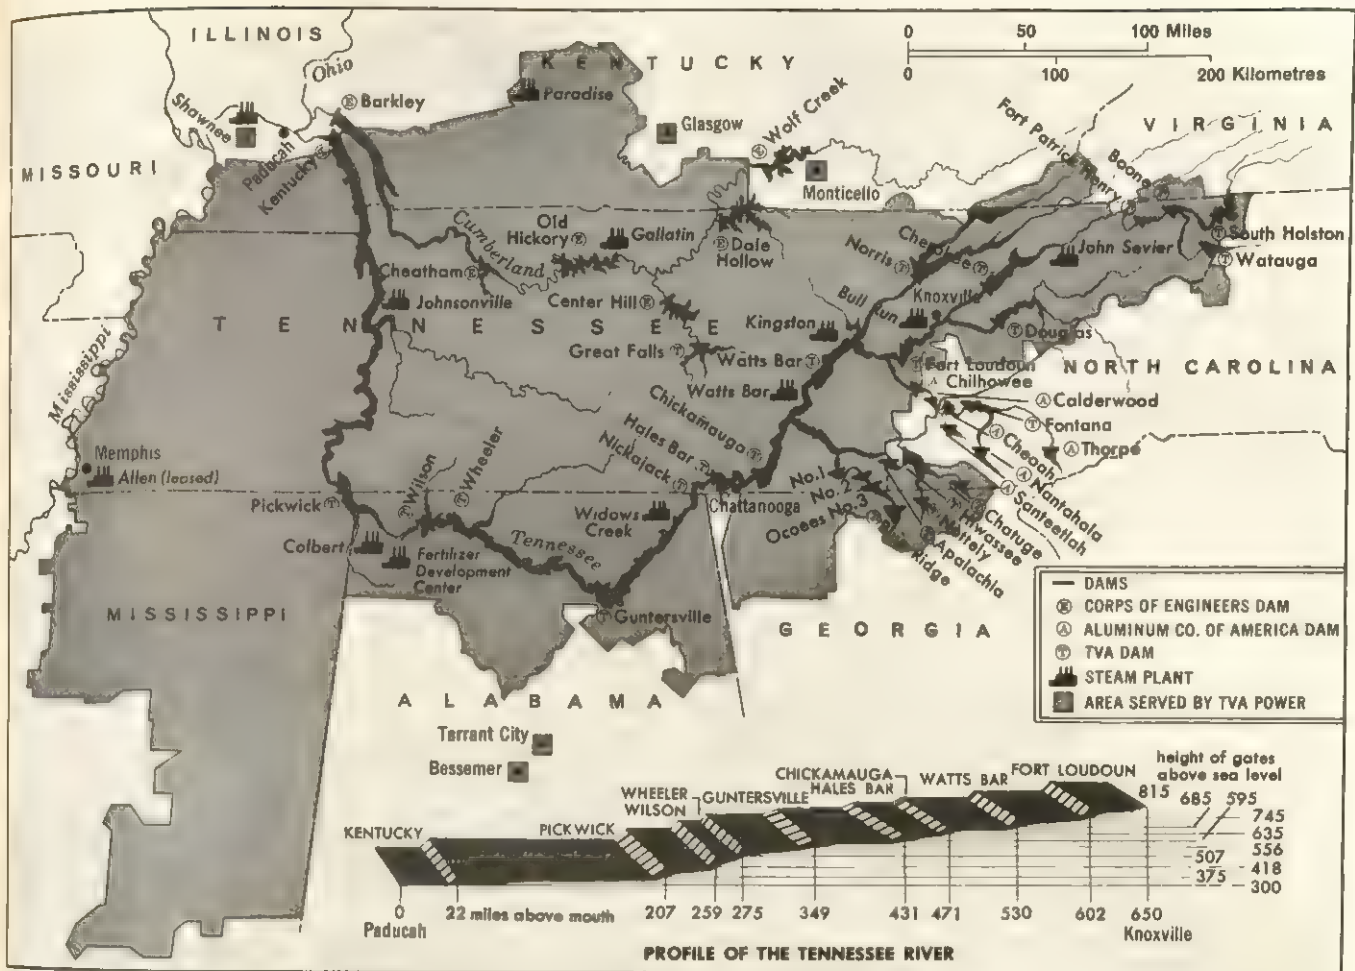

The Tennessee, fifth largest among U.S. rivers in volume of stream flow, provided a means of westward travel by American frontiersmen as early as 1800. Travel on the river was interrupted, however, at Muscle Shoals, Ala., where the river dropped approximately 100 ft. in the course of 20 mi. Early efforts by state and private interests to cope with the shoals met with failure or with only limited success. It was not until World War I that national attention was drawn to the Tennessee. At that time the U.S. government determined to erect two nitrate manufacturing plants at Muscle Shoals for the manufacture of munitions; these plants were to free the nation from dependence on Germany and Chile for nitrates. The government also determined to construct a dam on the river to supply hydroelectric power to run the nitrate plants, along with a steam-electric plant to provide additional power. None of these undertakings had been finished by the end of the war, when it was decided to suspend construction work, though Wilson dam was later completed. The government's investment in the Muscle Shoals properties up to 1918 was somewhat more than \$100,000,000.

In the next 15 years there were as many as half a dozen serious proposals for liquidating the government's investment at Muscle Shoals. Some failed to reach the action stage and congress refused to approve others. Two bills providing for government development of the properties were approved by congress, but were vetoed by the president. In 1933, two unusual circumstances combined to produce a decision on the question: (1) in that year the country was in the depths of a great depression; (2) Pres. Franklin D. Roosevelt strongly favoured a course regarding the Muscle Shoals properties that would put idle men to work and stimulate the economy of the region. These circumstances, placed against the background of a long history of frustration and delay, were sufficient to cause congress to pass a bill introduced jointly by Sen. George W. Norris of Nebraska and Rep. Lister Hill of Alabama to establish the Tennessee Valley authority. The bill was signed by President Roosevelt on May 18, 1933.

The act established the TVA as a regional agency of the U.S. government. In legal form the authority was a public corporation; though it was a governmental agency it had many of the attributes of a private corporation. The TVA established its administrative headquarters at Knoxville, Tenn. It was governed by a board of three directors appointed by the president by and with the advice and consent of the senate. The TVA normally employed somewhat more than 15,000 people. The greatest concentrations of TVA personnel were in Knoxville and Chattanooga, Tenn., and at Muscle Shoals, Ala.

**The TVA Program.**—Those who drafted the TVA act visualized that agency as something approaching a federal department of natural resources for the Tennessee valley. The program outlined for the new agency did not contemplate for it any new or startling powers; for most of the things it was to do were already being done, in the Tennessee valley and elsewhere, by a host of governmental agencies. What was new about the TVA was that its activities were to be focused on a river drainage basin, and that they were to be brought together in the hands of a single agency. The TVA, then, represented a new approach to

AREA SERVED BY THE TENNESSEE VALLEY AUTHORITY

the administration of natural resources in the United States.

The 1933 act, recognizing water as a basic natural resource, gave the TVA three broad, basic powers over the Tennessee river: (1) it was directed to take such action as might prove necessary to control floods on the river; (2) it was required to develop navigation on the river; (3) it was instructed to produce and market electric power "so far as [may prove] consistent with such purposes." The constitutionality of the TVA was immediately challenged but was upheld by the supreme court in the case of *Ashwander v. TVA* (1936) and in later decisions.

The TVA eventually operated 32 major dams, 9 of them on the main stream of the Tennessee and 23 on its tributaries. Of this total the TVA built 21; it purchased a few from a private power company; and a few, originally built and owned by a private industry, were operated by the authority as part of its river control system. (The TVA also marketed electric power from five dams constructed by the U.S. army corps of engineers on the Cumberland river, but since these are in another drainage basin they are not considered here.) All dams in the system were managed as a unit, with emphasis first of all on flood control. It was, of course, not possible to avoid all floods, for that would have required complete control of every minor tributary stream, which was not economically practicable. Large floods, however, were prevented; no major flood damage occurred on the Tennessee river after the system of dams was completed.

Navigation, the second major responsibility of the TVA, increased markedly after 1933. In that year the river carried little commercial traffic: mainly short-haul bulk items such as sand and gravel. The TVA built navigation locks into each of its nine main dams, deepened and otherwise improved the channel, and encouraged both local governments and private businesses to develop port facilities along the river. As a result, river traffic increased from 33,000,000 ton-miles in 1933 to 600,000,000 in

1950 and more than 2,000,000,000 in the 1960s.

A third major activity named in the 1933 act, the production and sale of electric power, was a highly controversial issue and was resisted by privately owned power companies. At first it was confined to the output of the turbines installed in the big dams. In carrying out this function, the TVA entered into contracts with municipalities and co-operatives to supply wholesale power for distribution and joined with them in purchasing the facilities of privately-owned electric utility companies in the region. These purchases established an integrated power service area in which the TVA was the sole supplier of power. To the end of World War II, and for several years thereafter, hydroelectric plants supplied most of the power. The continuing growth of power requirements for homes, farms and industry, together with a vast expansion in power requirements for defense plants such as those of the Atomic Energy commission, made necessary the extensive construction of steam plants. In 1950, 90% of the power produced by the TVA system came from the big dams, but by 1962 this had shrunk to about 25%. The decrease in the percentage of hydroelectric power was accounted for by the big new steam-electric plants built after 1950. One of these plants was the largest of its kind in the United States and another was the second largest. They consumed a total of about 18,000,000 tons of coal a year.

In the 1960s the TVA power system, which included 48 dams and several steam plants, possessed a generating capacity of nearly 12,000,000 kw. TVA sold its power in bulk, almost half of it to federal agencies, principally the Atomic Energy commission; of the remaining half, about one-third went to large industries, which were served directly, and about two-thirds to 155 locally-owned municipal and co-operative distribution systems. Electric rates in the Tennessee valley, reflecting the economies resulting from the authority's emphasis on mass markets, were among the lowest

in the nation. Critics of TVA asserted that its rates were lower than those of privately owned utility companies because the TVA was not subject to taxation and was not obligated to make a profit on its operations. The TVA power system was financed by appropriations from congress, by corporate earnings, and (after 1960) by electric power bonds. A schedule of payments was eventually worked out by which over a period of years the TVA would refund to the national treasury all federal electric power investment in the valley. Some critics were not satisfied with such arrangements and argued that the whole project should be sold to private industry.

Another major provision of the 1933 act made the TVA responsible for the operation of the nitrate plants at Muscle Shoals. As nitrates can be used in the manufacture of both munitions and fertilizers, the TVA developed the Muscle Shoals plants into a vast laboratory for the development and production of experimental fertilizers. The TVA did not produce fertilizer for commercial sale.

The 1933 act also charged the TVA with responsibility for improving forestry practices in the region. In pursuance of this directive the authority conducted studies of forest conditions and forest practice, produced and distributed hundreds of millions of pine seedlings, and worked closely with governmental forest agencies and with forest industries throughout the basin.

Two auxiliary but nevertheless important program activities are worthy of notice. First, construction of the "Great Lakes of the South" resulted in a vast increase in recreational opportunities in the valley. The TVA played an active part in developing these opportunities and in encouraging the practice of outdoor recreation. As a consequence, such activities as boating, fishing, and camping, known only in rudimentary form in 1933, increased sharply. Recreation, indeed, assumed the proportions of a major industry.

A second important auxiliary activity was found in the authority's health program. By co-operating with state and local agencies and conducting a vigorous mosquito control program on its reservoirs, the TVA participated in the eradication of one of the area's most dread diseases. In a region where malaria had been endemic, no case of malaria traceable to the river was reported after 1948.

**Methods of Work.**—Two outstanding features characterized TVA's approach to the regional administration of natural resources. First was application of the principle of multiple use throughout the watershed. It is possible to develop a river for the single purpose of preventing flooding, or of promoting navigation, or of producing electric power; but it is also possible to develop it for all three purposes simultaneously, and for other subsidiary purposes as well. In 1933 there were very few multiple-use water installations in the United States, and there was no river basin to which the multiple-use principle was applied in its entirety. In this respect the TVA was a unique institution in U.S. river basin development.

TVA's operating methods were unique in yet a second important respect. Instead of building the agency into a regional super-government, the TVA board of directors decided to work, to the maximum degree possible, through the valley's existing governments—the states, counties and municipalities. This made for an intricate network of agreements and contracts among the governments of the basin covering a wide variety of activities, such as health, forestry, agriculture, parks and other recreational facilities, navigation and electric power. The TVA thus became one of the foremost practitioners of co-operative administration to be found in the United States.

The TVA is held in high esteem in other countries. Some 3,000 foreign visitors, many of them high government officials, visit the valley each year to see for themselves how the TVA operates and what it has achieved. It has been the inspiration for similar projects in other lands—in India, for example, with its Damodar valley development, and in Colombia with its Cauca river project. The TVA inspired no similar river valley developments in the United States, though a number of principles that it developed were put into operation in various river basins.

Clapp, *The TVA: an Approach to the Development of a Region* (1955); Tennessee Valley Authority, *TVA: the First Twenty Years*, ed. by Roscoe C. Martin (1956).

**TENNIEL, SIR JOHN** (1820–1914), English illustrator and satirical artist, especially known for his work in *Punch* and his illustrations for *Alice in Wonderland*, was born in London on Feb. 28, 1820. Although he became a probationer, and then a student of the Royal Academy, he soon left the schools, where at that time there was little teaching. In 1836 he sent his first picture to the exhibition of the Society of British Artists and in 1845 contributed a 16-ft. cartoon to the competition of designs for mural decoration of the new Palace of Westminster. For this he received £100 and a commission for a fresco in the Upper Waiting hall (or "Hall of Poets") in the house of lords. He was already known and appreciated as a humorist and his early companionship with Charles Keene fostered and developed his talent for caricature.

In 1850 he was invited by Mark Lemon to fill the position of joint cartoonist (with John Leech) on *Punch*, in succession to Richard Doyle. Gradually he took over altogether the weekly drawing of the political "big cut," which John Leech was happy to resign into his hands in order to restrict himself to his pictures of life and character. Leech's work consisted for the most part of farce; Tenniel's was high comedy and not infrequently tragedy; and the freedom of the humorist heightened the severe beauties of the satirist. When Leech died his friend continued his work alone.

About 2,300 cartoons, innumerable minor drawings, double-page cartoons for *Punch's Almanac* and other special numbers and 250 designs for *Punch's Pocket-books* comprise the sum of Sir John Tenniel's work for the periodical in the service of which he spent the greater portion of his life. His most famous cartoon was probably "Dropping the Pilot" (1890), on the subject of Bismarck's resignation.

In his drawings for *Punch* he raised the political cartoon into a classic composition from which a sense of nobility is never absent. It was in recognition not only of his ability as an artist in black and white but of his service in infusing good humour into one phase of political life that a knighthood was conferred upon him in 1893. He retired in 1901. He illustrated many books and his drawings for *Alice's Adventures in Wonderland* (1866) and *Through the Looking-Glass* (1870) gained him international fame and immortality.

See *Cartoons by Sir John Tenniel* (1901); and M. H. Spielmann, *History of Punch* (1895).

**TENNIS.** Two games bearing the name tennis are closely connected by origins but are widely different. One, "lawn tennis," may be regarded as the descendant of the other, which is sometimes termed "royal tennis," "real tennis" or simply "tennis" in England but is called "court tennis" in the U.S. Lawn tennis, generally called tennis in the U.S., is the more popular and will be considered first.

#### LAWN TENNIS

As an independent member of the family of ball games of which the parent root probably developed in Egypt or Persia, 500 years before the Christian era, lawn tennis is relatively modern and it

PHOTOGRAPHED FROM A WOODCUT IN THE BRITISH MUSEUM BY JOHN R. FREEMAN AND CO.

"DROPPING THE PILOT," CARTOON BY TENNIEL COMMENTING ON THE FORCED RESIGNATION OF OTTO VON BISMARCK FROM THE GOVERNMENT OF KAISER WILLIAM II OF GERMANY

(H. Es.)

had its beginning in England. It is played by men and women, at night as well as day, indoors as well as outdoors, on various surfaces—dirt, grass, clay, concrete, asphalt, wood and composition.

In 1874 an Englishman, Maj. Walter C. Wingfield, devised and applied for a patent for a "new and improved portable court for playing the ancient game of tennis." Wingfield's court was wider at the base lines than at the net and so often referred to as the hourglass court, and the game was introduced as Sphairistiké, shortened to Stické, or as its enemies liked to call it, "Sticky." The court was set up outdoors, on the grass, and under the new name tennis-on-the-lawn or lawn tennis its popularity quickly grew. About this time the All England Croquet club, located in Wimbledon, a suburb of London, discovered that its exchequer was empty, or almost so, and added the term "Lawn Tennis" to its title and several grass courts to its facilities. The first championship was held on these Wimbledon courts in June 1877, on a rectangular surface measuring 78 ft. long and 27 ft. wide, with a net 3 ft. 3 in. high at the centre. There were 22 competitors, of whom the majority were either court tennis or rackets players. The winner, Spencer W. Gore, was a former rackets star and a native of London.

It is interesting to note that the dimensions of the lawn tennis singles court remained unchanged after that time. In 1878 the height of the net was set at 4 ft. 9 in. at the posts, and 3 ft. at the centre. In 1880 the net was lowered to 4 ft. at the posts, and in 1884 to 3 ft. 6 in.

From the start until 1907, the championships at Wimbledon were won by natives of the British Isles. The early Wimbledon, however, with its bleacherless courts and general air of calm, bore little resemblance to its successors. Yet from the start the All England club had a decisive influence on the game. The Lawn Tennis association (English) was founded in 1886, the International Lawn Tennis federation not until 1912. In the interim, the game had spread to other continents.

Lawn tennis was said to have been introduced into the United States by Miss Mary E. Outerbridge, who spent the winter of 1874 in Bermuda and there saw the game played by British officers of the garrison. She returned with a lawn tennis net, some rackets and balls, obtained from the regimental stores through the courtesy of the colonel. One of her brothers, A. Emilius Outerbridge, helped her lay out a court on the grounds of the Staten Island Cricket and Baseball club. James Dwight and F. R. Sears, Jr., of Boston, Mass., obtained a tennis set from England and laid out a court at Nahant, a seaside resort in Boston harbour, a little later. The first tournament in the United States, a handicap event, was played at Nahant in Aug. 1876. The first official championships of the United States, playing under English rules and with English balls, was held at the Casino, Newport, R.I., on Aug. 31, 1881. There were 25 competitors entered in the singles and 13 pairs in the doubles. The singles was won by Richard D. Sears of Boston, who held the title every year until 1888. In 1881, the United States National Lawn Tennis association, with Gen. R. S. Oliver of the Albany Tennis club as president, was formed.

This period might be called the age of innocence of lawn tennis. In both England and the United States, the players were amateurs and sportsmen, the tournaments few in number, and watched by small galleries. In the United States, from the time of Sears until 1900, most U.S. champions were volleyers, Oliver S. Campbell and Robert D. Wrenn, who held between them seven singles titles in the 1880s and 1890s, especially so. During this period the game was played chiefly along the eastern seaboard. In 1900 a cup was donated by Dwight F. Davis, then an undergraduate at Harvard, for international competition. (From the start, all Davis Cup competitions consisted of four singles and one doubles match.) The first contest was played in Longwood, near Boston, on Aug. 8, 9 and 10, 1900, and was won by the United States, three matches to none. (One was not played, and one left unfinished.)

In 1907, Norman E. Brookes of Australia became the first overseas player to win the Wimbledon men's title. Meanwhile in the United States there was a swing away from the net game. Both William A. Larned, who held the U.S. title from 1907 to 1912,

and William T. Tilden, who dominated world tennis from 1920 to 1925, were able to play the net and play it well. Yet both won the majority of their titles from the base line. In 1912 a new influence was felt in the game. For the first time in U.S. tennis the champion did not come from the eastern seaboard. That year the title was won by Maurice E. McLoughlin, a Californian trained on courts of asphalt. He introduced the cannon ball service, a weapon used by every U.S. star since then.

By this time tennis may be said to have come of age. In 1915 the national championships of the United States were removed from the tranquillity of the Casino at Newport, R.I., to the urban setting of the West Side Tennis club at Forest Hills, Long Island. Attracted by the spectacular playing of McLoughlin, crowds turned out for the matches. At the same period, interest grew in the Davis Cup matches. In 1903, when it had been captured by the Doherty brothers, R. F. and H. L., for Great Britain at the Longwood Cricket club, in Brookline, Mass., only two nations were represented, and hardly 2,000 spectators saw the contests each afternoon. In 1914, seven nations from three continents competed, and the challenge round played at Forest Hills just after World War I broke out was witnessed by 10,000 people. Australia with the left-handed veteran Brookes, and Capt. Anthony Wilding (killed in action in Flanders in 1915) met McLoughlin and R. Norris Williams, an undergraduate at Harvard. There have perhaps been greater matches in tennis history; but few so dramatic, so grim or so spectacular. The speed of shots on both sides was tremendous. The rallies were few. It was a different style from the tennis played by the Dohertys which was based on accuracy rather than sheer speed. Tennis had changed as the world was changing.

Tilden won the title at Wimbledon in 1920, the first but not the last male American to do so. He repeated the next year, and in 1923 the first Californian, William M. Johnston, won the men's singles. In 1920 Tilden and Johnston beat the Australians at Auckland, N.Z., taking the Davis Cup back to the United States. With Williams and Vincent Richards they formed the best balanced team ever to appear on a court in an international match, and through their efforts Australian, Japanese and French challengers for the trophy were regularly defeated until 1927. The U.S. influence on sport at this period was visible in many ways. Money was now an important factor in competitive tennis. Huge crowds attended national championships and Davis Cup matches in every land. As an example, the old grounds seating several thousand spectators under wooden roofs at the Worple road, Wimbledon, were abandoned in 1921 for a new, modern, concrete tennis stadium, one mile away, seating 15,000. This stadium which was opened by King George V on June 22, 1922, attracted players

from Spain, France, the United States, Italy, Ireland, Scotland, Sweden, Holland, South Africa, Belgium, Rumania, Denmark, Greece, New Zealand, Australia and England that summer. It cost £140,000, and was probably paid for in a few years. Likewise in 1923 the wooden stands of the West Side Tennis club at Forest Hills were replaced by a concrete stadium seating more than 13,000. The first Wightman Cup matches inaugurated the stadium.

By this time young Frenchmen were advancing in the technique of the game, and a French team composed of J. R. Lacoste, J. Borotra, H. Cochet and J. Brugnon (the "Four Musketeers") reached the challenge round of the Davis Cup for the first time in 1925. Two years later they were the survivors of 25 nations, and crossing the ocean found themselves for the third time challenging the holders, the United States, at Philadelphia, Pa. This time they discovered that age had stemmed the power of the two great U.S. stars, Tilden and Johnston. They carried the cup back to France. This was the first of six years of French successes in tennis.

In 1933, a total of 32 different countries challenged France for the Davis Cup. The trophy was finally won by Great Britain, who defeated the French in the challenge round at Paris. For the first time in 20 years this international sporting cup was returned to the land which gave the game birth.

With its young stars Fred Perry and "Bunny" Austin, Great Britain was in the driver's seat until the arrival of another star from California, J. Donald Budge. Perry had won three successive championships at Wimbledon (1934-36) and three times at Forest Hills (1933, 1934 and 1936).

Budge not only succeeded Perry as Wimbledon and U.S. champion but set a new record when in one year (1938) he won the four major singles championships of the world—Australia, France, Great Britain and the United States. One of Budge's most noted victories was his defeat of Baron Gottfried von Cramm, German star, in the deciding match of the Davis Cup Interzone final at Wimbledon in 1937. Tilden declared afterward that it was one of the finest matches he had even seen. Von Cramm won the first two sets and Budge evened the score. Then the German took a commanding 4-1 lead in the final set, but Budge again pulled even and finally, after having had five match points in the 14th game, he won it for the set and match. Budge again defeated Von Cramm in the 1937 final at Forest Hills to win his first U.S. championship.

The loss of Budge to the professional game in 1938 after he had repeated his Wimbledon, Forest Hills and Davis Cup victories proved to be a severe blow to U.S. Davis Cup play. In 1939 Robert L. Riggs, who had won at Wimbledon and was to become

U.S. champion about ten days later, and Frank Parker, who had two years of challenge round experience, lost the cup after they had led Australia 2-0 in the challenge round tie at Merion Cricket club, Haverford, Pa.

So again, as in 1914, Australia captured the Davis Cup as World War II halted international competition, this time for six years. Bombs damaged the Wimbledon grounds and other clubs throughout Europe. In the United States, the U.S. Lawn Tennis association helped keep tennis alive during the war. The development of junior tennis, a major activity of the USLTA, was emphasized and a nationwide program provided opportunities for thousands of boys and girls under 18 years of age to learn the game.

The USLTA championships were held during the war period. Most of the leading players were in the armed forces but a few on furlough or stationed near Forest Hills competed with the younger players. The wartime champions included: (in U.S. navy) Lt. Donald McNeill; Seaman Robert L. Riggs; Lt. Frederick R. Schroeder, Jr.; and Lt. Joseph R. Hunt (killed in a plane accident); and Sgt. Frank A. Parker (U.S. army).

After the war interest in the game revived quickly throughout the world. In 1946, 20 nations challenged for the Davis Cup which had been held since 1939 without competition by Australia. The Americans won 5-0 in Melbourne and retained the cup for the next three years at Forest Hills. John A. ("Jack") Kramer, Frederick R. ("Ted") Schroeder, Frank A. Parker and Richard A. ("Pancho") Gonzales were the outstanding Americans during these four years and none of them lost a singles match in these challenge rounds.

The public, so long starved of the glamour of top tennis entertainment, flocked to the major championships. At Wimbledon the first winner was the tall Frenchman Yvon Petra, but the U.S. provided the next five winners, all of whom were players of great character and individuality of style. Kramer, later to amass the greatest fortune ever made from the game as a professional player and promoter, was the "power-player" par excellence; the tall, and promoter, was the "power-player" par excellence; the tall, Robert Falkenburg relied on service speed and volleying the return; Schroeder based his game on a superb net attack and an invulnerable backhand, coupled with remarkable stamina; J. Edgar ("Budge") Patty possessed an immaculate touch, while Richard Savitt put his trust in service power and heavily hit ground strokes. Another great American of this era was Gonzales, who won his national title at Forest Hills in 1948 and 1949. He turned professional at the then unusually young age of 21 and making his new status became the world's greatest player of the 1950s, and, in the view of many, the greatest player yet seen.

In 1950 the balance of power swung back to Australia. The fine athletic physique and speed play of Frank A. Sedgman and his doubles partner, Kenneth B. McGregor, won back the Davis Cup for Australia and this partnership retained the trophy in 1951 and 1952, in which latter year Sedgman had already won at Wimbledon. In 1951 this partnership won all four of the major doubles championships—an achievement without precedent.

Despite the loss of two such fine players to the professional ranks in Jan. 1953, the Australians were able to replace them by the 18-year-olds Lewis A. Hoad and Kenneth R. Rosewall from Sydney. Much of the credit for Australia's extraordinary feat of continuing to hold the Davis Cup in these circumstances went to the shrewd captaincy of Harry Hopman.

The more mature and experienced Americans E. Victor Seixas and M. Anthony Trabert, who had won Wimbledon and the U.S. title respectively in 1953, recaptured the Davis Cup in 1954 at Sydney in front of a world record crowd of 25,600 on the opening day. But only eight months later the Australians, tuned to concert pitch by Hopman, beat the same American team at Forest Hills by 5-0. Australian domination was consistent except for the successful American raid at Brisbane in Dec. 1958 when Alejandro Olmedo, a Peruvian by birth, succeeded in beating the Australians Ashley J. Cooper and Malcolm J. Anderson, and, in partnership with Hamilton F. Richardson Anderson and Neale A. Fraser in the doubles.

The U.S.-Australian monopoly of the top honours was first breached during the 1950s by Jaroslav Drobný, exiled from Czechoslovakia, whose amazing repertoire of strokes, including his remarkable left-handed flexibility overhead, won him the French title in 1951 and 1952 and the Wimbledon crown in 1954 in a memorable final of a record number of 58 games against Rosewall.

After Drobný followed other Europeans in Sven Davidson (Sweden), Kurt Neilsen (Denmark), Nicola Pietrangeli (Italy) and Manuel Santana (Spain), all of whom appeared as winners or finalists in the major championship finals.

In 1955 Trabert won three of the major championships and then turned professional and the following year Hoad repeated this feat but was defeated in the U.S. final by his compatriot, Rosewall. After their successful Davis Cup defense in 1956 Rosewall turned professional and Hoad followed him into the paid ranks immediately after becoming the first postwar player to retain a Wimbledon men's singles title.

This left another young Australian, Ashley Cooper, as the world's leading amateur player and in 1958 he won the Australian, Wimbledon and U.S. championships, leaving only the French title to his elder and left-handed compatriot, Mervyn Rose.

For the next two seasons major honours were shared by Pietrangeli, Olmedo and the left-handed

Neale Fraser. Two new stars emerged in 1960 from Queensland, Rodney G. Laver and Roy Emerson. In 1962 Laver achieved the elusive "grand slam" of all four major championships which had been captured only by Donald Budge in 1938, as already noted.

Laver turned professional after Australia's successful defense of the Davis Cup in 1962 to pit his maturing skill against Rosewall, who had inherited the mantle of Gonzales as the world's leading exponent. In 1963 Charles R. (Chuck) McKinley captured the Wimbledon title for the United States for the first time in eight years and, teamed with Dennis Ralston, went on to take the Davis Cup from the Australians, 3-2, at Adelaide in Dec. 1963. Australia regained the cup in Sept. 1964, at Cleveland, O., with Emerson and Fred Stolle over McKinley and Ralston, 3-2. Ralston became a professional in 1966.

A feature of the 1950s and 1960s was the advance of the Latin-American countries. The Peruvian Alex Olmedo was the first player from his continent to win a major singles championship when he won the Australian title in 1959 and followed this by capturing the Wimbledon crown. He was followed in 1963 by Rafael Osuna of Mexico, who won the U.S. championship and had been a member of his country's Davis Cup team, which upset all tradition by beating the United States in 1962, and reached the challenge round against Australia. In 1965 Santana became the first Spanish player to win the U.S. championship, and the first

continental European since Henri Cochet of France in 1928. And in Davis Cup play, Spain, represented by Santana, Juan Gisbert, Luis Arilla and Juan Couder, won the European Zone for the first time in history and went on to defeat the U.S., American Zone winner, and India, Eastern Zone victor, to reach the challenge round against Australia. In 1966 Brazil upset the U.S. to win the American Zone but was defeated by India, which in turn lost to Australia.

A new system for ranking players and designating a player of the year on the basis of performance in the Wimbledon, U.S., French, Australian, and Italian championships went into effect in 1967.

**Women Players.**—Tennis was played by women from the start; but their entry into competitive tournaments was delayed, and it was not until 1884, seven years after the championships began, that Maud Watson became the first woman's champion at Wimbledon by winning from an entry of 13 players. In the United States a tournament for women was held at the Philadelphia Cricket club, and was won by Ellen Hansell in 1887. This tournament was held again in 1888 and it became the first official championship for women in 1889. It was won by Bertha Townsend. Elisabeth Moore, later singles champion, described the costumes of the period in this way: "The girls were wearing lawn dresses with leg of mutton sleeves, sailor hats, and ornamental tennis shoes. My dresses, which were of white lawn, swept just clear of the grass on ordinary shots; but brushed it when I stooped."

In those days the game was played chiefly from the base line. In England the standard of play was and remained for some time much higher than in the United States, yet women still served underhand. In 1904 a new star appeared, May Sutton, a girl of 16 and the first of a long line of Californian champions who revolutionized U.S. and world tennis. She was gifted with a strong constitution and a heavily topped forehand drive which enabled her to win the American title that year, and also to defeat Miss D. K. Douglass (afterward Mrs. Lambert Chambers) at Wimbledon in 1905, thus becoming the first American ever to capture an English title. She again defeated her rival to win the championships in 1907, and 22 years later she returned to Wimbledon and reached the quarter finals of the singles in a strong field.

An important influence on the game for women was Suzanne Lenglen, a French girl who first appeared at Wimbledon in 1919. Born at Compiègne, France, in 1899, she won her first championship at St. Cloud in 1914. Between 1919 and 1926 she dominated the game, winning at Wimbledon six times.

The next leading player was Helen Wills, later Helen Wills Moody Roark. She played Mlle Lenglen only once, at Cannes in 1926, when she was a young girl, losing 6-3, 8-6. Like her rival she had every stroke, supported by a more powerful forehand drive, the weapon of every champion. She had a matchless record in competitive tennis, winning the first of her seven American titles in 1923 and the first of her eight Wimbledon titles four years later.

Another great woman player, also an American and a Californian, was Alice Marble. Despite illnesses which would have discouraged most players, she ended as Wimbledon and U.S. titleholder in 1939. She was the first woman champion to develop a really hard service and possessed an all-round game to which she added unusual severity at the net and overhead.

Miss Marble won her fourth and last U.S. championship in 1940, defeating for the third time the resolute Helen Jacobs, who had succeeded Mrs. Moody as U.S. titleholder in 1932 and as Wimbledon champion four years later. The next ten years failed to produce any great woman champion. During the war years Mrs. Sarah Palfrey Cooke, an easterner, and Pauline Betz, a Californian, led the field, Mrs. Cooke winning her second championship in 1945 and Miss Betz her fourth in 1946, after which they turned professional and Margaret Osborne duPont, Louise Brough, Doris Hart and Shirley Fry, sometimes referred to as "the big four," dominated the game at Forest Hills, Wimbledon and in other countries wherever they competed, including France, England, South Africa and Australia. Then in 1951 Maureen ("Little Mo") Connolly from California, like Miss Sutton in 1904, took complete com-

mand, winning the first of three successive U.S. championships at Forest Hills before she had reached her 17th birthday. Miss Connolly was the second youngest player to capture the title. Miss Sutton was only a few days younger when she won the championship in 1904 and Miss Wills was almost a year older when she captured her first U.S. title in 1923.

On her first attempt at Wimbledon in 1952 Miss Connolly won the crown and successfully defended it in 1953 and 1954. In 1953 she also won the Australian, French and United States titles and so this mistress of ground stroke play became the first woman to hold the four major championships simultaneously. She sustained a leg injury while horseback riding which prevented her from defending her United States title in 1954. Later Miss Connolly, perhaps the only player of the postwar era to rank with Suzanne Lenglen and Helen Wills Moody Roark, became a professional.

Doris Hart won the U.S. championship in 1954 and retained it in the following year when Louise Brough had recaptured the Wimbledon title after an interval of five years. In 1956 Althea Gibson of New York became the first Negro player to win a major title when she won the premier hard court title in the world—the French championship—at Paris. She was the dominating player for the next two seasons, notably by reason of her service power winning both the Wimbledon and U.S. championships. The U.S. strength in depth weakened at this time and the British trio of Angela Mortimer (1955), Shirley Bloomer (1957) and Christine Truman (1959) won the French championship, as did the Hungarian Suzy Kormoczy in 1958.

The first player to break the 13-year-old postwar U.S. monopoly of the Wimbledon and U.S. championship titles was Maria Bueno, a superb stylist from Brazil. She won both these championships in 1959 with artistic ease and retained her Wimbledon title in 1960. She, however, lost her American title to her doubles partner, Darlene R. Hard of California. Miss Hard had already won the French championship that year, and went on to retain her U.S. title in 1961 following the severe illness of Miss Bueno.

In the season of 1961 two British players won major championships: Ann Haydon took the French title and Angela Mortimer became the first British singles winner at Wimbledon for 24 years.

Margaret Smith, a player of rare physique and power, won the Australian championship in 1966 for the seventh consecutive time. In 1962 Miss Smith took the French and United States championships but Karen Susman (U.S.) won at Wimbledon. In 1963 Miss Smith lost her French title to her compatriot, Lesley Turner; became the first Australian woman ever to win Wimbledon; but lost her U.S. championship to Miss Bueno, who won both at Forest Hills and Wimbledon in 1964, when Miss Smith won in Italy and France. In 1965 Miss Smith won at Wimbledon and Forest Hills. Miss Bueno in Italy. In 1966 Miss Bueno won at Forest Hills. Billie Jean King at Wimbledon, and Ann Haydon Jones in France.

**Wightman Cup.**—In 1923 a cup was donated by Mrs. George Wightman, the former Hazel Hotchkiss of California and herself national singles champion of the United States in 1909, 1910 and 1911 and winner of some 47 other U.S. titles, for competition between teams of women players from the United States and England. The Wightman Cup was first contested at Forest Hills, Long Island, on Aug. 11 and 13, 1923. The annual contest is held alternately in the two countries, with five singles and two doubles matches. The first contest was won by the United States. By 1930 each side had won on four occasions: but then the United States' team won for the next nine years until the competition was abandoned in 1940 owing to the war. After the war the United States' dominance was even more pronounced, producing a string of 12 more consecutive victories, and never losing more than two of the seven rubbers. The British girls, with Christine Truman contributing to three wins, succeeded for the first time in 28 years at Wimbledon in 1958 by the minimum margin of 4-3 and repeated this performance in 1960. In 1961 the United States recaptured the Cup and held it through the mid-1960s.

**The Federation Cup.**—A new international competition for the women's team tennis championship of the world was inaugurated with the Federation Cup by the ILTF in honour of its 50th anniversary in 1962. The first competition for the cup, held at

the Queen's club, London, in 1963 was won by the U.S. team when Billie Jean Moffitt and Darlene Hard beat the top-seeded Australian team of Margaret Smith and Lesley Turner in the doubles finals. (J. R. Tu.; E. S. Br.; R. McW.)

### STANDARD GRIPS AND STROKES

Many outstanding players and coaches have written books and manuals on how to play tennis, a few of which are listed in the *Bibliography*, below. The following descriptions of the standard grips and strokes originally were prepared by Tilden, one of the all-time great players, for the United States Lawn Tennis association's *Official Tennis Guide*, 1942 (*Official Tennis Guide with the Official Rules*, 1942, copyright 1942 by A. S. Barnes and Co.). Tilden's instructions have been revised only to comply with subsequent changes in the rules (see *Rules of Lawn Tennis*, below).

(X.)

**Forehand Ground Stroke Grip.**—Hold the racket as if it were standing on the edge of the frame, the handle pointing toward you, the short strings perpendicular to the ground, the long strings parallel to it. Then "shake hands" with it—literally. The handle settles comfortably into your palm. Close your fingers tightly around the handle. The racket is then, or should be, part of the straight line of your arm. There should be no angle at your wrist. The hand rests along the outside, or right side, of the handle, the thumb and fingers wrapped around the handle, naturally and comfortably. The racket thus becomes an extension of the arm that can be moved as easily as if it belonged there.

**Backhand Ground Stroke Grip.**—Obviously, the forehand grip, as described in the foregoing paragraph, is impossible for a backhand shot, since it would be swung against the back of the hand itself. Therefore, a change is necessary. Move the hand one-quarter of a circle on the handle, backward, so that the hand rests directly on top of the handle, the knuckles of the hand pointing to the sky. Grip the handle tightly. If it is more comfortable to run the thumb up the handle, do so. If not, wrap it around as in the forehand grip. The shot off the backhand travels directly across the wrist with this grip. Swing freely from the shoulder with both these grips and keep the wrist stiff and locked on all drives. The grip is about the same for a volley.

**Service Grip.**—The grip for service is just midway between the forehand and the backhand grip. Take your forehand grip and then turn the hand half way back to the backhand position. On all grips, hold the racket tight at the moment of impact with the ball. Loosen your grip between shots so as not to cramp the hand from too great a strain.

**Forehand Drive.**—The forehand drive is one continuous swing, which is considered in three sections:

The speed of the shot is decided by the length of the swing behind the body. The farther back you start your swing the faster the racket will move forward, and the speedier your shot will be.

The direction of your stroke, whether it is hit straight or cross court, is determined by that portion of the swing in front; that is, alongside your body. In other words, as you face off court, it is the space within the lines from your hips. If you meet the ball back near your right hip, the shot goes toward the right; if you meet it directly in front of the belt buckle, it goes on a straight line; and if you meet it up in front of your left hip, the shot goes cross court to your left.

When awaiting the ball, face your opponent across the net. As soon as you see the ball coming toward you, decide which side, fore or backhand, you will play it. Then change your body position accordingly so that you face off the side line, while your shoulders are along the line of the shot you are going to make. As the ball reaches you, drop your weight to your back foot and commence your swing well behind your body, meeting the ball with the racket in its forward flight just in front of your body and follow through to the end of your swing.

This brings us to the third portion of the swing, the portion beyond or nearer the net than the body, which is called the follow-through. This determines the spin or twist on the shot and is the factor that holds the ball in court. For the drive the racket meets the ball flat and passes up and over the top of the ball,

thus spinning the ball away from you and downward. It is the same spin as a pitcher's drop in baseball. The racket passing under the ball, making it float or drag, is the "chop" or "slice" stroke (see below).

The swing, as described, is in three parts, but is made in one free movement that carries the whole body along with it. It is as essential in tennis to follow through from the beginning of your swing to the extreme end of your reach as it is in golf or baseball. It gives direction and control of length.

There is a certain height at which to hit a tennis ball correctly. There are other heights at which one should never hit it unless caught out of position. The drive should be hit at a height never lower than your knees or higher than your shoulders. If the ball must be met at either of these heights, do not drive. Merely defend it and put it back and wait for another chance to drive. The height at which a tennis ball may be driven hardest is about waist high and at a distance about three feet from your body.

In making the drive, first be certain your form is correct. See to it that your feet are correctly placed so that you are sideways to the net. Next make sure your racket face meets the ball flat and that your racket passes up, over and slightly outside the ball, thus pulling it toward you. Do not try to hit hard until you have learned to hit correctly. Speed will come later, but correct form can be learned only before you have formed bad habits in stroking that are almost impossible to break.

**Backhand Drive.**—The laws of footwork are exactly the reverse of those applying to the forehand drive. The back foot is now the left, while the front foot is the right. The swing is from well behind the body, as in the forehand shot. The grip, as previously explained, is changed one-fourth on the handle, so that the hand is on top of the handle, while the shot travels across the wrist, which is locked and stiff. The racket head should be slightly in advance of the hand when it meets the ball, and the face of the racket is flat. The ball travels across the short strings. There is less top spin to this stroke than the forehand, because the follow-through is less. Use your left hand as a balance, well behind your body, and be sure to keep your body well away from the ball, so as not to cramp your swing. Bend to meet the ball with the racket head slightly on the side away from you and pull it toward you cross court.

**Service.**—Service is the "opening gun" in tennis. It is putting the ball in play, and every man should learn a service that will be a distinct advantage. Service has made many players famous. Maurice E. McLoughlin, the "California Comet," was world renowned for his service. Robert Lindley Murray, Elia Fottrell, Harold Throckmorton, S. Howard Voshell and many other players were noted for their services. All these men hit their deliveries hard, but they never sacrificed accuracy to mere speed. They were always careful to put the ball in court. They served very few double faults.

Foot faults should be avoided. The easiest way to serve legally is to remember that one foot must be on the ground behind the line and the other foot must not touch inside the court until your racket has struck the ball. Stand at least six inches behind the base line and you will not foot fault.

**Slice Service.**—This is the most common form of service. It requires the least effort and has the greatest chance of going in court.

To hit this service, stand behind the base line with your feet at an angle of about 45° to the line. Drop your weight back on your right foot. Toss the ball well above your head and slightly to the right in advance of it. Swing your racket up and forward with one rhythmic movement, at the same time shifting the weight forward toward the left foot. Meet the ball as high above your head as you can comfortably reach. The racket face is outside, or on the right side of the ball, and slightly over it. It travels from right to left. Swing directly through this, imparting a twist to the ball to spin it from left to right. This tends to hold the ball in court.

**American Twist Service.**—The stand and grip for this service are the same as for the slice. The ball is thrown slightly to the

When the ball is in play, a player fails to make a good return and loses a point if the ball bounces on the ground twice before he returns it; if his return lands outside any of the lines bounding his opponent's court; if he touches the ball with his racket more than once in making a return or if the ball touches him or anything he wears or carries, except his racket; if he or his racket or anything he wears or carries touches the net, posts, cord or wire, strap or band, or the ground within his opponent's court; or if he volleys the ball before it has passed the net.

**Scoring.**—The receiver scores a point if the server delivers a double fault. After the service, either player or side scores a point if the opposition fails to make a good return of the ball. A game is won by one side scoring at least four points; the first point is 15, the second is 30, the third is 40 and the fourth is game point.

A game must be won by at least two points, so that after a tie score at three points, or 40-40 (deuce), one side must score two consecutive points to win. The first point scored after deuce is called vantage, advantage or simply "ad." If the other side wins the next point the score returns to deuce. A score of zero is called love; e.g., 30-love is 30-0.

A set consists of one side winning at least six games. A tie score at five games is a deuce set, after which one side must win two consecutive games to win the set.

In major tournament play (i.e., championships and Davis Cup tournaments), a match consists of three out of five sets for men; two out of three for women.

#### THE DOUBLES GAME

**The Court.**—As shown in fig. 1, the doubles court is 36 ft. wide,  $4\frac{1}{2}$  ft. wider on each side than the singles court. Those portions of the singles side lines that lie between the service lines are called the service side lines (those portions of the singles side lines between service lines and the base lines may be omitted if desired). The server may stand anywhere behind the base line between the centre mark and the doubles side line.

**Order of Serving and Receiving.**—The pair who will serve in the first game of each set decide which partner will do so, and the opposing pair decide similarly for the second game. The partner of the player who served in the first game serves in the third; and the partner of the player who served in the second game serves in the fourth. The players continue throughout the set to serve in that order. Similarly, each pair decide which shall receive the first service by the opponents, the other receiving the second, and they continue in that order.

**Play.**—The rules applying to the play of the singles game apply also to doubles. A fault is incurred as in singles, and also if the ball served touches the server's partner or anything he wears or carries; but, if the service is not a let, and touches the receiver's partner or anything he wears or carries before it hits the ground, the server wins the point.

After the service, either partner of the opposing pairs may return any shot, but if his partner should touch the ball with his racket their opponents win the point. (E. S. Br.)

#### ROYAL OR COURT TENNIS

**History.**—Court tennis may well be called a royal game, having been popular with various kings of England and France. In the ball games of the Greeks and Romans may be seen the rudiments of the French *jeu de paume*, which is the ancestor of modern tennis in a direct line. The origin of the name is quite obscure. The most probable derivation is from the word *Tenez!* (Take it! Play!), especially in view of the large number of French terms that adhere to the game; e.g., grille, tambour (drum, from the sound on the board that formed the face of that buttress) and *dedans*. Further, a poem dealing with the game, written in Latin elegiacs by R. Frissart, makes the striker cry "*Excipe!*" (Take it!) before each stroke; this seems to correspond with the custom which enjoins the rackets marker to call "play" whenever a legitimate stroke has been made.

In the *Alexiad* of Anna Comnena (about A.D. 1120) is a reference to a game played on horseback in which a staff, curved at the

THE BETTMANN ARCHIVE INC.

FIG. 2.—COPPER ENGRAVING OF EARLY COURT TENNIS, 1612. AT THIS DATE THE RACQUET WAS IN USE BUT THE NET HAD NOT YET REPLACED THE FRINGED OR TASSELED ROPE STRETCHED ACROSS THE COURT. NOTE LE PETIT TROU AND LA LUNE, "WINNING OPENINGS" ON THE FAR END WALL

end and strung with strings of plaited gut was used. This game was played in a court called "a court for goff" (*sic*; according to the *Lexicon of Alexandrine Greek*) and some similar game, corrupted through *tchangan* into *chicane*, was played in France. Good authorities also find a more ancient derivation of the game in Egypt, in Persia and among the Arabs before Charlemagne. In A.D. 1300 the game was also known as *La Boude*. Throughout the century indeed it was played in France and by the highest in the land. Louis X died from a chill contracted after playing, and Charles V was devoted to the game. In England the game, or some form of it, was known, Chaucer alluding to it in the words "But canstow playen racket to and fro."

The 16th century was the golden age of court tennis in France. Francis I built a magnificent court at the Louvre, where his son Henry II, one of the best players of his day, built a second and larger court. Charles IX was a keen player and granted a royal charter to the Corporation of Tennis professionals. Henry IV was equally keen and in 1596 there were said to be 250 courts in Paris alone. An English visitor in 1598 wrote "There be more tennis players in France than ale-drinkers or malt-wormes (as they call them) with us." Louis XIII and Louis XIV both played tennis but by 1657 the number of courts in Paris had declined to 114. The Royal tennis court at Versailles was the scene of the famous tennis court oath of June 20, 1789, which marked the start of the French Revolution.

In England, too, court tennis was in its heyday in the 16th century. Henry VII was a good player and played on courts in Woodstock, Wycombe, Westminster, Sheen and Windsor. At Windsor in 1506 he entertained the king of Castile who played a tennis match against the marquis of Dorset. Henry VIII was an outstanding tennis player and in 1530 built the court at Hampton Court palace which is still in use. He also built four courts at Whitehall and one at St. James's palace. Elizabeth I was a keen spectator. Charles I and Charles II were both good tennis players. Charles II built a magnificent new court at Whitehall and Pepys made several allusions to the king playing tennis. A print of 1641 shows James II as a boy in a tennis court. Tennis in England declined in the 18th century and in the second half of the 20th century there were 15 courts in play.

In the late 19th century courts were built in Australia at Hobart (1854) and Melbourne (1882) which are still in play.

Court tennis was introduced to the U.S. in the 1870s. The game was played regularly at the Racquet Court club in New York in 1876 where Robert Moore was the professional instructor. The club merged about 1890 with the Racquet and Tennis club, which became the foremost club in America sponsoring court tennis and other racquet games. Courts were built in Boston, Mass. (the first in 1876), Newport, R.I. (1880), Chicago, Ill. (1893), and later at Tuxedo, N.Y.

It is possible to trace a world's open championship of court

tennis back to the early 19th century and holders of this title have been: 1816, Marchisio (Italy); 1819, Philip Cox (Great Britain); 1829, J. E. Barre (France); 1862, E. Tompkins (Great Britain); 1871, G. Lambert (Great Britain); 1885, Tom Pettitt (United States); 1896, P. Latham (Great Britain); 1905, C. Fairs (Great Britain); 1907, P. Latham (Great Britain); 1908, C. Fairs (Great Britain); 1912, G. F. Covey (Great Britain); 1914, J. Gould (United States); 1922, G. F. Covey (Great Britain); 1928, P. Etchebaster (France); 1955, J. Dear (Great Britain); 1957, A. Johnson (Great Britain); 1959, N. R. Knox (United States).

Peter Latham had the distinction of being world champion of rackets also. Jay Gould and N. R. Knox are the only amateurs ever to have won the world championship. Pierre Etchebaster, a French Basque and professional at the New York Racquet and Tennis club, held the title for 27 years until he retired at the age of 60 undefeated, and was undoubtedly the outstanding player of the modern era.

**General Description of Game.**—Court tennis is played on a four-walled indoor court somewhat larger than a lawn tennis court (see fig. 3). Although there is no standard size, the following dimensions may be regarded as suitable: the space enclosed by the walls, 110 ft. by 38 ft. 8 in.; the floor however, measuring but 96 ft. by 31 ft. 8 in., the difference being the width of a roofed corridor (the "penthouse") which runs along the two end walls and one of the side walls. Across the middle of the court a net is stretched and the first object of the game is to strike the ball over this with a racket. The net is 5 ft. high at the ends, 3 ft. at the middle, and divides the floor into two equal parts—the "service" side and the "hazard" side. The cement floor and walls should be smooth but not polished.

The height of the court to the tie beam is 30 ft. The height of the play line, above which the ball must not go, is 18 ft. at the sides and 23 ft. at the ends. The roof of the penthouse slopes downward toward the court, the lower edge being 7 ft. 1½ in. from the floor, the upper edge 10 ft. 7 in., the width 7 ft. The *dedans* is an open gallery in the wall at the service end of the court, under the penthouse. It is 21 ft. 8 in. in width; the upper edge is 6 ft. 10 in. from the floor, the lower edge 3 ft. 3 in. Looking from the *dedans*, the right-hand or main wall has one peculiarity, the *tambour*, a sloping buttress toward the far end, to form which the wall is built inward, reducing the breadth of that part of the court to 30 ft. 2 in. In the right-hand corner of the hazard side end wall (as viewed from the *dedans*) is the grille, an opening 3 ft. 1 in. square. The left-hand wall, along which runs the penthouse, is not continuous, being broken by a long opening between the floor and the penthouse similar to the *dedans*, and at the same height from the ground. The low walls under this opening and the *dedans* are called the batteries. There is no wall in front of the marker's box, through which the court is entered on either side of the net post. This long opening in the left-hand wall is divided into galleries and doors, the latter situated where the entrances to the court used to be in early courts. The galleries are marked by posts, which also serve to support the penthouse. The galleries, *dedans* and grille are known as the openings; three of these—the grille, *dedans* and winning gallery—are winning openings, for if a ball in play is struck into one of these, the striker scores a point. In the earlier French courts there were

other winning openings such as: *Vais* (the board), an upright board 9 ft. by 1 ft. in the left-hand corner of the *dedans* wall; *le petit trou* or *le trou*, a hole 16 in. square at the bottom of the other side of the wall; and *la lune*, a round opening high up by the play line, one at each end of the court. The court has certain lines painted on the floor which are also continued perpendicularly on the walls. On the hazard side is the half-court line, the pass line and the service line. The first is required in doubles or in certain forms of handicap game. The pass line is drawn 7 ft. 8 in. from the main wall, the service line 21 ft. 1 in. from the grille wall. The rectangle contained by the pass and service lines forms the service court. The other lines, both on the hazard side and service side, mark the chases, which will be explained below.

**Equipment.**—The balls vary in the three countries where the game is chiefly played—England, United States and France. In England balls weigh approximately 2½ oz. and are 2¼ in. in diameter. They are made of strips of cloth wound tightly together, tied with twine and covered with white melton cloth. The French ball is harder and faster than the English; and the American ball lies somewhere between the two. The racket is usually about 27 in. long and weighs about 16 oz. The head is about 9 in. long and 6 in. broad, but there are no restrictions as to size or weight. The head is somewhat pear-shaped, but its centre line does not correspond with the centre line of the handle, since the head is curved upward. Some of the early rackets were strung diagonally (i.e., in diamonds); later, vertical-horizontal stringing was universally adopted; then followed knotting at the points of intersection, a practice which later disappeared.

**Scoring.**—A match in England and the U.S. consists ordinarily of the best of three or the best of five sets, a set being scored by the player who gets six games first. Sets of "eight games," i.e., the set won by the player who gets eight games first, are generally played in France.

Occasionally vantage sets are played; i.e., when each player has scored five games or seven games as the case may be, the set continues until one player gets an advantage of two games. In these conditions sets sometimes continue for a very long time, and sets where over 60 games have been played are recorded. In matches for the world's championship the best of 13 sets of six games are generally played on three different days with an interval between them. Scoring is as in lawn tennis. The score of the player who won the last stroke or made the last chase is called first.

**The Game.**—The players decide who shall serve by spinning a racket on its head. One spins and the other calls "rough" or "smooth," the rough side of the head of the racket showing the knots of some of the lower strings. The winner takes the service side, service being an advantage. In four-handed games the winners of the spin often take the hazard side, since by doing so they can decide which of their opponent's service each one will elect to take. He serves from any part of the court and in any way he thinks best, and the ball must go over the net, strike the side penthouse, and fall into the service court. His opponent ("striker-out") tries to return the ball over the net before it has touched the ground a second time; he may volley or half-volley (strike the ball as soon as it touches the court) his return. For a stroke to be good, it must be made before the second bounce of the ball, and the ball must go over the net (even if it touches it), and must not strike the wall above the play line, nor touch the roof or rafters.

**The Chase.**—The chase is an ancient and somewhat complicated device which gives some advantage to skill over brute force. In most games a player has to return the ball either on the volley or after it has bounced once; a ball that bounces twice is called "not up." In court tennis this is not so and a ball that is "not up" makes a chase at the point where it strikes the ground on its second bounce. Neither player scores a point when a chase is made; the point goes into cold storage until it is played off, either when one player has reached 40 or when there are two chases in cold storage in the same game. When this happens the players change ends and play off the chase or chases. The nearer the chase is to the back wall, the better it is and the more difficult it is to beat. This is where skill is at a premium. The player who

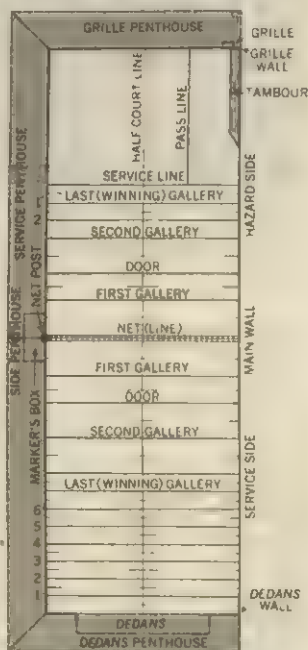

FIG. 3.—PLAYING AREA FOR COURT TENNIS

allowed the ball to bounce a second time and make a chase now has to make a better chase to win the point. If any stroke he makes in the course of the rally is going to make a worse chase, his opponent can leave it and thereby win the point.

The marker standing by the net is responsible for calling out the score and for naming the chases. To enable him to mark the chases the floor of the court is ruled off in transverse lines. On the service side these start at one-yard intervals from the back wall and are numbered from one to six. From chase six to the net further lines are ruled, corresponding to the centre of the galleries which line the side wall and called by the name of the gallery to which they refer, i.e., last gallery, second gallery, door, first gallery and line. A ball entering directly into one of these galleries makes a chase in exactly the same way as when the ball bounces twice. On the hazard side there are no chase lines at the back of the court and a ball "not up" in this area loses a point as in other games. The galleries are the same as on the service side except that the equivalent of the last gallery is called the winning gallery and a ball entering it rings a bell and wins a point outright. Under the winning gallery there are two chase lines marked one and two.

**T. TENNYSON, ALFRED TENNYSON, 1ST BARON** (1809–1892), often regarded as the chief representative of the Victorian Age in English poetry, was born at Somersby, Lincolnshire, on Aug. 6, 1809. The Tennysons were an old Lincolnshire family whose prosperity had been established by the poet's grandfather, George Clayton Tennyson of Bayons Manor. George Clayton the elder preferred his second son, Charles, to his eldest, George Clayton the younger (1778–1831), whom he disinherited, and who took orders, married Elizabeth Fytche (1781–1865), and was presented to the rectory of Somersby.

Alfred, the fourth of his 12 children, was sent in 1815 to Louth Grammar School—where he was unhappy—with two of his brothers, Frederick and Charles. He left in 1820, but, though home conditions were difficult, his father managed to give him a wide literary education. Alfred was precocious and before his teens had composed in the styles of Thomson, Pope, Scott, and Milton. To his youth also belongs *The Devil and the Lady* (first published in 1930), which shows an astonishing understanding of Elizabethan dramatic verse. Byron was a dominant influence; at the news of his death (1824) he flung himself on the ground in a passion of grief and carved on sandstone "Byron is dead."

At the lonely rectory the children were thrown upon their own resources. All writers on Tennyson emphasize the influence of the Lincolnshire countryside on his poetry, the Wolds, the plain, the sea about his home, "the sand-built ridge of heaped hills that mound the sea," "the waste enormous marsh."

In 1824 the health of Tennyson's father began to break down, and he took refuge in drink. Alfred, though depressed by unhappiness at home, continued to write, collaborating with Frederick and Charles in *Poems by Two Brothers* (1826; dated 1827). His contributions (more than half the volume) are mostly in fashionable styles of the day.

In 1827 Alfred and Charles joined Frederick at Trinity College, Cambridge. There Alfred made friends with Arthur Hallam, the gifted son of the historian Henry Hallam. This was the deepest friendship of Tennyson's life. The friends became members of "The Apostles," an exclusive undergraduate club of earnest intellectual interests. Tennyson's reputation as a poet increased at Cambridge. In 1829 he won the Chancellor's Gold Medal with a poem called *Timbuctoo*. In 1830 *Poems, Chiefly Lyrical* was published, and in the same year Tennyson, Hallam, and other Apostles

went to Spain to help in the unsuccessful revolution against Ferdinand VII. Tennyson took away many vivid memories, especially of the scenery of the Pyrenees. In the meantime Hallam had become attached to Tennyson's sister Emily but was forbidden by his father to correspond with her for a year.

In 1831 Tennyson's father died. Alfred's misery was increased by his grandfather's discovery of his debts. He left Cambridge without taking a degree, and his grandfather made financial arrangements for the family. In the same year Hallam published a eulogistic article on *Poems, Chiefly Lyrical* in the *Englishman's Magazine*. He went to Somersby in 1832 as the accepted lover of Emily.

In 1832 Tennyson published another installment of his poems (dated 1833), including "The Lotus-Eaters," "The Palace of Art," and "The Lady of Shalott." Among them was a satirical epigram on the critic "Christopher North" (John Wilson Croker; q.v.), who had attacked *Poems, Chiefly Lyrical* in *Blackwood's Magazine*. Tennyson's sally prompted a scathing attack on his new volume in the *Quarterly*. The attacks distressed Tennyson, but he continued to revise his old poems and compose new ones.

In 1833 Hallam's engagement was recognized by his family, but while on a visit to Vienna he died suddenly (Sept. 15). The shock to Tennyson was severe. It came at a depressing time; three of his brothers, Edward, Charles, and Septimus, were suffering from mental illness, and the bad reception of his own work added to the gloom. Recent research has shown that his frustrated courtship of Rose Baring and his attachment to Sophy Rawnsley increased his psychological difficulties. Yet it was in this period that he wrote some of his most characteristic work, "The Two Voices" (of which the original title, significantly, was "Thoughts of a Suicide"), "Ulysses," "St. Simeon Stylites," and, probably, the first draft of "Morte d'Arthur." To this period also belong some of the poems that became constituent parts of *In Memoriam*, and lyrics later worked into *Maud*.

In May 1836 his brother Charles married Louisa Sellwood of Horncastle, and at the wedding Alfred fell in love with her sister Emily. For some years the lovers corresponded, but Emily's father disapproved of Tennyson because of his bohemianism, addiction to port and tobacco, and latitudinarian religious views, and in 1840 he forbade the correspondence. Meanwhile the Tennysons had left Somersby and were living a rather wandering life nearer London. It was in this period that Tennyson made friends with many famous men, including Gladstone, Landor, and Carlyle. Carlyle, writing to Emerson in 1842, described him as

a man solitary and sad, dwelling in an element of gloom, carrying a bit of Chaos about him, which he is manufacturing into Cosmos . . . One of the finest-looking men in the world. A great shock of rough, dusky, dark hair; bright, laughing hazel eyes; massive aquiline face, most massive yet most delicate; of sallow brown complexion, almost Indian looking, clothes cynically loose, free-and-easy, smokes infinite tobacco. His voice is musically loose, fit for loud laughter and piercing wail, and all that may lie between; speech and speculation free and plentiful; I do not meet in these last decades such company over a pipe!

Edward FitzGerald, another friend, at this time felt, despite the poet's "humours and grumpiness," "a sense of depression . . . at the overshadowing of a so much more lofty intellect than my own."

In 1840 Tennyson invested his patrimony in a project for wood-carving by machinery. Its failure plunged him into financial difficulty; and family worries, besides his ill health and nervous instability, brought him near to a breakdown. But the then fashionable "water cure," which he took several times during the

THE GRANGER COLLECTION

TENNYSON. PHOTOGRAPHED ABOUT 1861

1840s, seems to have done him good, for we hear of his resuming his port-and-tobacco regime.

In 1842 he published *Poems*, in two volumes, one containing a revised selection from the volumes of 1830 and 1832, the other new poems. The new poems included "Morte d'Arthur," "The Two Voices," "Locksley Hall," and "The Vision of Sin," and other poems that reveal a strange naïveté, such as "The May Queen," "Lady Clara Vere de Vere," and "The Lord of Burleigh." The new volume was not on the whole well received. But the grant to him at this time, by Sir Robert Peel, of a pension of £200 helped to alleviate his financial worries.

To this period belongs the strange poem *The Princess*, a serio-comic fantasy on the higher education of women, which appeared in 1847, to the usual accompaniment of unfavourable reviews. It sold well, however, and this encouraged Tennyson to take up an old project of writing an Arthurian epic.

The year 1850 marked a turning point. Tennyson resumed his correspondence with Emily Sellwood, and their engagement was renewed and followed by marriage. Meanwhile Edward Moxon offered to publish the elegies on Hallam that Tennyson had been composing over the years. They appeared, at first anonymously, as *In Memoriam*, which had a great success with both reviewers and the public, won him the friendship of Queen Victoria, and helped bring about, in the same year, his appointment as laureate.

After his marriage, which was happy, Tennyson's life became more secure and outwardly uneventful. There were two sons: Hallam (1852-1928) and Lionel (1854-86). The times of wandering and unsettlement ended in 1853, when the Tennysons took a house, Farringford, in the Isle of Wight. Tennyson was to spend most of the rest of his life there, and at Aldworth, near Haslemere, Surrey, which he built as a summer home in 1868.

His position as the national poet was confirmed by his ode on the death of Wellington (1852)—though the critics at first thought it disappointing—and the famous poem on the charge of the Light Brigade at Balaclava, published in 1855, first in the press and then in the *Maud* volume. *Maud* itself, a turbid and unsatisfactory "monodrama," provoked a storm of protest; many of the poet's admirers were shocked by the morbidity, hysteria, and bellicosity of the hero. Yet *Maud* was Tennyson's favourite.

His Arthurian project at last issued in *Idylls of the King* (1859), which had an immediate success. Tennyson, who loathed publicity, had now acquired a sometimes embarrassing public fame. The *Enoch Arden* volume of 1864 perhaps represents the peak of his popularity. New Arthurian *Idylls* were published in *The Holy Grail, and Other Poems* in 1869 (dated 1870). These were again well received, though some readers were beginning to show discomfort at the "Victorian" moral feeling that Tennyson had imported into his source material from Sir Thomas Malory.

In 1874 Tennyson decided to try his hand at poetic drama. *Queen Mary* appeared in 1875, and an abridged version was produced at the Lyceum in 1876 with only moderate success. It was followed by *Harold* (1876; dated 1877), *Becket* (not published in full until 1884), and the "village tragedy," *The Promise of May*, which proved a failure at the Globe in November 1882. This—his only prose work—shows Tennyson's growing despondency and resentment at the religious, moral, and political tendencies of the age. He had already caused some sensation by publishing a poem called "Despair" in the *Nineteenth Century* (November 1881). It evoked a parody by Swinburne, who had already laughed at the muzzy metaphysics of the laureate's "Higher Pantheism"; and a stream of pamphlets, lectures, and sermons. A more positive indication of Tennyson's later beliefs appears in "The Ancient Sage," published in *Tiresias and Other Poems* (1885). Here the poet records his intimations of a life before and beyond this life.

Tennyson accepted a peerage (after some hesitation) in 1884. In 1886 he published a new volume containing "Locksley Hall Sixty Years After," consisting mainly of imprecations against modern decadence and retracting the earlier poem's belief in inevitable human progress. This challenge to the Liberal thought of the day prompted Gladstone to write a protesting article in the *Nineteenth Century* for January 1887.

In 1889 Tennyson wrote the famous short poem "Crossing the

Bar," during the crossing to the Isle of Wight. In the same year he published *Demeter and Other Poems*, which contains the charming retrospective "To Mary Boyle," introducing "The Progress of Spring," a fine lyric written much earlier and rediscovered, and "Merlin and the Gleam," an allegorical summing-up of his poetic career. In 1892 his play *The Foresters* was successfully produced in New York. Despite ill health, he was able to correct the proofs of his last volume, *The Death of Oenone . . . and Other Poems*. He died at Aldworth on Oct. 6, 1892.

**Assessment.**—Tennyson was revered by most Victorians as the greatest poet of his time, both for his mastery of verse technique and his "message." He was also admired for his accurate depictions of nature. In the 20th century, however, many readers have become less enamoured of his verse technique, which they have found, though sometimes exquisite, very limited; they feel that Tennyson does not realize anything like the full strength of the English language, and the famous Tennysonian "music" has come to seem too much a matter of removing s's and mouthing out hollow o's and a's. As for the "message," it is sometimes thought obscure, and more often vague, trite, or "dated," while the poet's passion for botanical detail has become wearisome.

Adverse critics have tended to accept the intuitions of Fitzgerald and Carlyle that Tennyson did not put enough of himself into his poetry. They remark on the contrast between the mellifluous, polished, Victorian-Hellenistic verse and the poet who wrote it, the unconventional recluse with the manners of a Lincolnshire peasant-farmer. Henry James, who met Tennyson in old age, made the discovery that "Tennyson was not Tennysonian." His art seemed to be too much one of exclusion. This point was made by Ezra Pound, who quoted Walter Bagehot's rhetorical question, "Is it credible that Tennyson's whole mind should be made up of fine sentiments?" and continued:

Of course it wasn't. It was that lady-like attitude toward the printed page that did it—that something, that ineffable "something," which kept Tennyson out of his works. When he began to write for Vicky's ignorant ear he immediately ceased to be the "Tennyson so muzzy" that he tried to go out through the fireplace," the Tennyson with the broad North accent, the old man with the worst manners in England (except Carlyle's), the Tennyson whom "it took the whole combined efforts of his family and his publishers to keep respectable." (*The Literary Essays of Ezra Pound*, ed. by T. S. Eliot. All rights reserved. Reprinted by permission of New Directions Publishing Corp., U.S.; A. V. Moore, U.K. and Commonwealth).

Much more sympathetic criticism, however, can also be found among post-Victorian writers on Tennyson. G. K. Chesterton, in *The Victorian Age in Literature* (1913), admirably suggests the pleasures to be savoured in Tennyson's "magical luck or skill in the mere choice of words—"Wet sands marbled with moon or cloud"—"Flits by the sea-blue bird of March"—"Leafless ribs and iron horns"—"When the long dun wolds are ribbed with snow"—in all these cases," says Chesterton, "one word is the keystone of an arch which would fall into ruin without it." Chesterton also speaks of strong phrases that suggest Virgil: "Tears from the depth of some divine despair"—"There is fallen a splendid tear from the passion-flower at the gate"—"Was a great water; and the moon was full"; lines which "do not depend on a word but on an idea." Chesterton considers, surely rightly, that Tennyson was "first and last a lyric poet."

A more influential critique is T. S. Eliot's essay on *In Memoriam* (in *Essays Ancient and Modern*, 1936). Eliot considers Tennyson a great poet because of his "abundance, variety and complete competence." He stresses Tennyson's metrical accomplishment: "without making the mistake of trying to write Latin verse in English, he knew everything about Latin versification that an English poet could use." Eliot agrees with earlier critics that Tennyson is not a master of the long poem; *Maud* and *In Memoriam* "are each a series of poems," *The Princess* is "an idyll that is too long," the *Idylls of the King* "are no different in kind from some of his early poems"; these poems are descriptive and picturesque rather than narrative. Eliot finds that "The fury of *Maud* is shrill rather than deep, though one feels in every passage the exquisite adaptation of metre to the mood. . . ." He places *In Memoriam* highest among Tennyson's major works.

While Eliot praises generously the range of Tennyson's technical accomplishment, he is perhaps unfair to the didactic content of *In Memoriam*. He accuses Tennyson of confusing the Christian hope of eternal life with belief in the inevitable progress of humanity. But it is part of the Christian faith to believe in the ultimate transformation of earth into paradise; and Tennyson's own belief that life is morally meaningless without hope of personal survival is reiterated in the poem. Eliot apparently objects to the lack of firm dogma in Tennyson's assertion of his hopes and admission of his doubts and fears; we may think that Tennyson here shows an unusual sensitiveness and honesty, when we reflect on the temptation to simplify experience in order to bring his poem to a more unequivocally comforting conclusion.

Persuasive as Eliot's essay is, it is still not easy to arrive at a satisfactory judgment on Tennyson's achievement as a whole and to determine where its centre lies. Tennyson lacks the interesting "prose" side that, in their different ways, Matthew Arnold, Gerard Manley Hopkins, and Hardy all have. Apart from some penetrating critical remarks in notes and memoirs, he can be judged only on his poetry, and it is not clear how much of this can be regarded as of intrinsic, as well as of historical, interest. Much of the praise of his contemporaries can be discounted; Tennyson flattered them, as they flattered him, with the conviction that theirs was a great age and he was its great poet. His least satisfactory work is often to be found on this "public" level. The Wellington ode is an impressive public utterance, but a good deal of it is continuous with a rather shallow cult, in other poems, of the "great broad-shouldered Englishman," which, if it contains an element of sincere simplicity, also permits simple-mindedness and, worse, some boasting and conceit. Tennyson's political poetry has not worn well. Then—again in the "popular" range of his work—there is, besides genuine naïveté, a certain false simplicity, which appears in "Dora" and in the (admittedly much better) *Enoch Arden*. The simplicity in these poems is too studied and artificial. Finally, the sentimentality of poems like "The May Queen," which was noted in Tennyson's own day, has not become more bearable with the years. Tennysonian pathos, even at its best (as in the late poem "Rizpah"), has a dangerously self-conscious note, and the sentimental strain in it can become so gross as to assimilate it to the melodramatic falsetto of "Locksley Hall" and the worst parts of *The Palace of Art* or *Maud*. Sometimes, too, this strained indulgence in the pathetic is associated with a mawkishness and silliness that are common in Tennyson's early work and to which his early reviewers did ample justice.

In considering the "classical" element in Tennyson's work we reach more satisfactory ground for praise. Tennyson's lifelong devotion to classical poetry, especially Virgil, produced many memorable lines and phrases, and his poems afford several instances of the successful "symbolic" treatment of classical subjects; "Ulysses" is perhaps the finest, but "Tithonus" and the earlier "Lucretius" have fine moments. Yet Tennysonian classicism is not altogether satisfying. It is too often merely a question of manner, of a skilful recalling of ancient poetry and a taste for picturesque decoration. The substance of his "classical" poetry is limited in a way analogous to the limitation of that "fine ear" that the poet so carefully cultivated.

Some modern admirers have laid stress on the realistic and comic aspects of Tennyson's work. About the latter, it may be said that FitzGerald was right when he said "Alfred cannot trifle." The realism, especially in the Lincolnshire dialect poems, is a more solid achievement, but we may doubt whether it is truly central in Tennyson's work as a whole.

Tennyson's mysticism, on the other hand, has received less attention, but is important. Tennyson was not gifted as a religious or philosophical thinker, and the strictly argumentative part of *In Memoriam* cannot engage most of us as it did the poet's contemporaries. But the mystical feeling for the past, together with an awed sense of the mystery of life, represents something profound in Tennyson, and without this capacity for wonder we should not have had "Crossing the Bar" or "Flower in the crannied wall." A complete judgment of Tennyson cannot be reached without considering the Romantic tradition of which he was the consoli-

dator, and which laid such stress on the specialized poetic region called "the soul." We should also, perhaps, have to know more than is at present known about his life during the 1830s and '40s. Some readers may be content to regard him solely as the poet of such poems as "The Bugle Song," in which he so exquisitely renders a human emotion through a rendering of the sights and sounds of nature. It is understandable that we should wish to see a greater poet than that in Tennyson, but we are then faced by the difficulty implied in his own admission that he had "nothing to say." Perhaps the Tennyson who had nothing to say is Tennyson after 1850, when the process of "pulling himself together" seems to have cut him off from the deepest sources of his poetic inspiration. Yet even in the earlier poems it seems significant that among the most admired are "Mariana" and "The Lady of Shalott," where the evocation of visual images and care for the management of sound are what most remain in the memory. It is in the most poignant passages of *In Memoriam*, in the most personally felt parts of *Maud*, in some of the lyrics he added in 1850 to *The Princess*, and in the unforgettable "Break, break, break," that Tennyson achieves his most distinctively personal poetry; these things are among the most sensitive expressions in English of the emotions of nostalgia, trouble, and grief. But they do not make him a poet on the grand scale. Where he tries to be one, where he is most consciously the spokesman of "the age," he strains his voice and coarsens his art. We may not agree wholly with FitzGerald that the 1842 poems are all that matter, but few of us now suppose that Tennyson had the resources to write the modern epic after which he hankered; the *Idylls* as a whole do not fulfill the promise of the early "Morte d'Arthur" and survive, like *The Princess*, only in short passages. Perhaps the most attractive work outside the dream-world poems and the poignant lyrics may be found in the vein of mellow personal poetry revealed in "The Daisy" and a few later poems. But these successes are somewhat marginal; and our conclusion may be that time will reduce the voluminous Victorian laureate to a place in our literature as modest—but as secure—as that of Thomas Gray.

**BIBLIOGRAPHY.**—The standard collected edition is published by Macmillan in 1 vol. (1894; frequently reprinted); there is also a 1-vol. edition in the "Oxford Standard Authors Series" (1953). To these should be added *Poems by Two Brothers* (1826, dated 1827; reprinted with additions, 1893); *Suppressed Poems . . . 1830-62*, ed. by J. C. Thomson (1904); and *The Devil and the Lady* (1930) and *Unpublished Early Poems* (1931), both ed. by C. B. L. Tennyson.

Willey, in *More 19th-Century Studies* (1956). (W. W. Ro.)

**TENREC (TENDRAC)**, an insect-eating mammal of the family Tenrecidae, confined to Madagascar. They are among the largest members of the order Insectivora, ranging in length from 12 to 16 in. The coat consists chiefly of bristles and hairs, with some flexible spines. The general hue is brown tinged with yellow. From 12 to 16 or even 20 young are produced at birth.

In habits tenrecs are nocturnal; they live in the brush in the mountain regions, and in the dry season they hibernate in deep burrows. The long flexible snout is used to root up worms and grubs, and ground insects form part of its nourishment. When fat before hibernation, tenrecs are much valued as food by natives. See INSECTIVORE.

**TENSOR ALGEBRA.** Tensors were invented to express geometric entities arising in the study of manifolds (see MANIFOLDS; TENSOR ANALYSIS). Since manifolds were originally considered only in the small in terms of co-ordinate systems, tensors were expressed in terms of functions involving many indices which obey certain transformation laws when the co-ordinate system is changed. Subsequently, a global study of manifolds resulted in an invariant treatment of tensors and their algebraic analysis. This

is the subject of tensor or multilinear algebra.

**Tensors and Vector Spaces.**—Technically, a tensor of type  $(s, r)$  is an element of a vector space  $V_{s, r}$  associated with a given vector space  $V$  of dimension  $d$ . Any basis of  $V$  induces a basis of  $V_{s, r}$  in terms of which every tensor  $T$  in  $V_{s, r}$  can be represented by its components

$$T_{i_1 i_2 \dots i_s}^{j_1 j_2 \dots j_r}, \quad i_1, i_2, \dots, i_s, j_1, j_2, \dots, j_r = 1, \dots, d$$

The vector space  $V_{s, r}$  can be constructed from  $V$  in the following way: Let  $V^*$  denote the dual space of  $V$ ; that is, the vector space of linear functions of  $V$ . Then  $V_{s, r}$  is the collection of scalar-valued functions of  $r + s$  variables,  $r$  of them in  $V^*$  and  $s$  of them in  $V$ , which are linear in each variable when the others are left fixed. Thus each  $T$  in  $V_{s, r}$  gives the scalar value  $T(v^1, \dots, v^r, a_1, \dots, a_s)$  for every  $v^1, \dots, v^r$  in  $V$  and  $a_1, \dots, a_s$  in  $V^*$ . If  $e^1, \dots, e^d$  is a basis of  $V$ , let  $\phi_1, \dots, \phi_d$  be the basis of  $V^*$  which is dual to  $e^1, \dots, e^d$  so that  $\phi_i(e^j) = 0$  if  $i \neq j$  and  $\phi_i(e^i) = 1$ . Because  $T$  is linear in each variable separately,  $T$  is completely determined by its values

$$T(e^{i_1}, \dots, e^{i_s}, \phi_{i_{s+1}}, \dots, \phi_{i_{s+r}}) = T_{i_1 i_2 \dots i_{s+r}}^{j_1 j_2 \dots j_r}$$

If  $\phi_{i_1} \otimes \dots \otimes \phi_{i_s} \otimes e^{i_{s+1}} \otimes \dots \otimes e^{i_{s+r}}$  is the tensor which gives the value 1 on  $(e^{i_1}, \dots, e^{i_s}, \phi_{i_{s+1}}, \dots, \phi_{i_{s+r}})$  and 0 for any other choice of basis vectors, then

$$T = \sum_{i_1, i_2, \dots, i_{s+r}} T_{i_1 i_2 \dots i_{s+r}}^{j_1 j_2 \dots j_r} \phi_{i_1} \otimes \dots \otimes \phi_{i_s} \otimes e^{i_{s+1}} \otimes \dots \otimes e^{i_{s+r}}$$

Suppose a different basis  $f^1, \dots, f^d$  of  $V$  had been chosen and suppose  $f^j = \sum_{k=1}^d a_k^j e^k$ . Then the dual basis of  $f^1, \dots, f^d$  is the set

of linear functions  $\Psi_1, \dots, \Psi_d$ , where  $\Psi_i = \sum_{k=1}^d b_k^i \phi_k$  and  $(b_k^i)$  is the inverse of the nonsingular matrix  $(a_k^j)$ . In terms of the new basis,  $T$  is represented by its components

$$T(f^{i_1}, \dots, f^{i_s}, \Psi_{i_{s+1}}, \dots, \Psi_{i_{s+r}}) = \sum_{k_1, k_2, \dots, k_{s+r}} a_{k_1}^{i_1} a_{k_2}^{i_2} \dots a_{k_s}^{i_s} b_{k_{s+1}}^{i_{s+1}} b_{k_{s+2}}^{i_{s+2}} \dots b_{k_{s+r}}^{i_{s+r}} T_{k_1 k_2 \dots k_{s+r}}^{j_1 j_2 \dots j_r}$$

Thus a tensor of type  $(s, r)$  can be described as a function of  $r + s$  indices depending upon a basis which obeys the transformation law in the last formula when the basis is changed. The advantage of the invariant definition of  $V_{s, r}$  (i.e., independent of a basis) is that it is applicable to the case where the scalars form only a ring and also to infinite-dimensional vector spaces. It is also aesthetically more pleasing. The description of  $T$  in terms of its components  $T_{i_1 i_2 \dots i_{s+r}}^{j_1 j_2 \dots j_r}$  is useful in explicit computations.

**Construction and Properties of Tensor Algebra.**—Two tensors can be multiplied to give another tensor. If  $T$  is a tensor of type  $(s, r)$  and  $\bar{T}$  is a tensor of type  $(\bar{s}, \bar{r})$ , then  $T\bar{T}$  is a tensor of type  $(s + \bar{s}, r + \bar{r})$ , where

$$T\bar{T}(v^1, \dots, v^s, v^{s+1}, \dots, v^{s+\bar{s}}, a_1, \dots, a_r, a_{r+1}, \dots, a_{r+\bar{r}}) = T(v^1, \dots, v^s, a_1, \dots, a_r) \cdot \bar{T}(v^{s+1}, \dots, v^{s+\bar{s}}, a_{r+1}, \dots, a_{r+\bar{r}})$$

In terms of a basis the components of  $T\bar{T}$  are

$$T_{i_1 i_2 \dots i_{s+r}}^{j_1 j_2 \dots j_r} \bar{T}_{i_{s+1} i_{s+2} \dots i_{s+\bar{s}+r}}^{j_{r+1} j_{r+2} \dots j_{r+\bar{r}}}$$

From this multiplication an associative algebra called the tensor algebra  $\mathcal{T}$  can be constructed over the vector space  $V$ . The elements of  $\mathcal{T}$  are the scalars together with the sum of all the spaces  $V_{0, r}$  for  $r = 1, 2, 3, \dots$ . Two tensors of type  $(0, r)$  and  $(0, \bar{r})$  can be multiplied by the rule above to give a tensor of type  $(0, r + \bar{r})$ . This rule together with the distributive law determines the multiplication in  $\mathcal{T}$ . The tensor algebra  $\mathcal{T}$  has these

properties, which characterize it completely:

1. It contains  $V = (V_{0,1})$  and a unity element, the scalar 1. The smallest algebra in  $\mathcal{T}$  containing  $V$  and 1 is  $\mathcal{T}$ .

2. If  $\mathcal{Q}$  is any associative algebra with unity, any linear mapping of  $V$  into  $\mathcal{Q}$  can be extended to a map of  $\mathcal{T}$  into  $\mathcal{Q}$  which preserves multiplication.

**Tensor Product of Vector Spaces.**—The multiplication of two tensors is a special case of the tensor product of vector spaces. If  $V_1, \dots, V_k$  are  $k$  vector spaces, their tensor product  $V \otimes \dots \otimes V_k$  is the vector space of scalar-valued functions in  $k$  variables in  $V_1, \dots, V_k$  respectively which are linear in each variable separately. If  $v^i$  lie in  $V_i$ ,  $i = 1, \dots, k$ , then their tensor product  $v^1 \otimes \dots \otimes v^k$  has the value  $v^1(\alpha_1)v^2(\alpha_2) \dots v^k(\alpha_k)$  on  $(\alpha_1, \dots, \alpha_k)$  in  $V_1^*, \dots, V_k^*$  respectively. The space  $V_{s, r}$  is the tensor product of  $V^*$  taken  $s$  times and  $V$  taken  $r$  times.

**Tensor Fields.**—The tensors which arise in the study of manifolds are obtained by attaching to each point of a smooth  $d$ -dimensional manifold a  $d$ -dimensional vector space, its tangent space or space of directional derivatives. The tensors considered are those associated with each tangent space. A tensor field of type  $(s, r)$  on a manifold is a function which assigns to each point of the manifold a tensor of type  $(s, r)$  associated with the tangent space at that point. If a co-ordinate system with co-ordinate functions  $x_1, \dots, x_d$  is chosen about some point  $m$  of the mani-

fold, then the directional derivatives  $\frac{\partial}{\partial x_1}, \dots, \frac{\partial}{\partial x_d}$  form a basis of

the tangent spaces of points near  $m$ . In terms of this basis, a

tensor field of type  $(s, r)$  has components  $T_{i_1 i_2 \dots i_{s+r}}^{j_1 j_2 \dots j_r}$  which are

functions of the co-ordinates  $x_1, \dots, x_d$ . On the whole, tensor analysis studies the analytical properties of tensor fields, while tensor algebra deals only with the algebraic properties of tensors associated with a fixed vector space.

**Associated Algebras.**—Closely related to the tensor algebra  $\mathcal{T}$  over a vector space  $V$  are several other algebras, the most important for geometric and topological applications being the Grassman or exterior algebra over  $V$ . In this algebra, the elements to be multiplied are skew-symmetric tensors. A tensor  $T$  of type  $(0, r)$  is skew-symmetric if  $T(\alpha_{\pi(1)}, \alpha_{\pi(2)}, \dots, \alpha_{\pi(r)}) = \epsilon(\pi)T(\alpha_1, \alpha_2, \dots, \alpha_r)$ ;  $\epsilon(\pi)$  is  $+1$  or  $-1$  depending upon whether the permutation  $\pi$  of the integers  $1, 2, \dots, r$  is even or odd. Any tensor  $T$  of type  $(0, r)$  can be made skew-symmetric by alternating it; i.e.,  $\text{ALT}_r(T)$  is skew-symmetric, where

$$\text{ALT}_r(T)(\alpha_1, \dots, \alpha_r) = \frac{1}{r!} \sum \epsilon(\pi) T(\alpha_{\pi(1)}, \dots, \alpha_{\pi(r)}), \text{ summed over}$$

all permutations  $\pi$  of the integers  $1, \dots, r$ . The exterior algebra  $\mathcal{Q}$  over  $V$  is the space of skew-symmetric tensors in  $\mathcal{T}$  where the multiplication is the product of two tensors made skew-symmetric. Thus if  $T$  and  $\bar{T}$  are skew-symmetric tensors of type  $(0, r)$  and  $(0, \bar{r})$  respectively,  $T \wedge \bar{T} = \text{ALT}_{r+\bar{r}}(T\bar{T})$  is a skew-symmetric tensor of type  $(0, r + \bar{r})$ . Under this multiplication  $\mathcal{Q}$  becomes an associative algebra with unity of dimension  $2^d$  which contains  $V = (V_{0,1})$  and in which  $v \wedge v = 0$  for each  $v$  in  $V$ .

An algebra with the symmetric tensors can be formed in a similar manner. A tensor  $T$  of type  $(0, r)$  is symmetric if  $T(\alpha_{\pi(1)}, \dots, \alpha_{\pi(r)}) = T(\alpha_1, \dots, \alpha_r)$  for every permutation  $\pi$  of the integers  $1, \dots, r$ . Any tensor of type  $(0, r)$  can be made symmetric, i.e.,  $\text{SYM}_r(T)$  is a symmetric tensor of type  $(0, r)$

where  $\text{SYM}_r(T)(\alpha_1, \dots, \alpha_r) = \frac{1}{r!} \sum T(\alpha_{\pi(1)}, \dots, \alpha_{\pi(r)})$ , the sum

taken over all permutations  $\pi$  of the integers  $1, \dots, r$ . The polynomial algebra over  $V$  is the space of symmetric tensors in  $\mathcal{T}$  where the multiplication is the product of two tensors made symmetric. Thus if  $T$  and  $\bar{T}$  are symmetric tensors of type  $(0, r)$  and  $(0, \bar{r})$  respectively, then  $T \times \bar{T} = \text{SYM}_{r+\bar{r}}(T\bar{T})$ .

A generalization of Grassman algebras called Clifford algebras

is important for the study of certain representations of orthogonal groups. If  $B$  is a symmetric tensor of type  $(2,0)$  over  $V$ , the orthogonal group of  $B$  is the group of nonsingular linear transformations  $l$  on  $V$  for which  $B(l(v), l(v)) = B(v, v)$  for all  $v$  in  $V$ . The Clifford algebra of  $B$ , which contains  $V$  and in which  $v \cdot v = B(v, v)1$ , is useful for studying the spin representations of this group. The Clifford algebra of  $B$  is constructed from  $\mathcal{V}$  in the following way: Let  $\mathcal{I}_B$  denote the ideal in  $\mathcal{V}$  generated by all elements of the form  $v^2 - B(v, v)1$  for  $v$  in  $V$ ; i.e.,  $\mathcal{I}_B$  is the set of all linear combinations of elements of  $\mathcal{V}$  of the form  $T(v^2 - B(v, v)1)$  or  $(v^2 - B(v, v)1)T$ . The Clifford algebra of  $B$  is the algebra  $\mathcal{V}/\mathcal{I}_B$ ; i.e.,  $\mathcal{V}$  with the elements  $\mathcal{I}_B$  set equal to zero. If the field of scalars is not of characteristic 2, and if  $e^1, \dots, e^n$  is a basis of  $V$ , then  $e^{i_1} \cdot e^{i_2} \cdot \dots \cdot e^{i_k}$  ( $i_1 < i_2 < \dots < i_k$ ) is a basis of the Clifford algebra, so that the Clifford algebra has dimension  $2^n$ . If  $B$  is identically zero, the Clifford algebra is the previously constructed Grassman algebra. See also DIFFERENTIAL GEOMETRY.

**TENSOR ANALYSIS.** The concept of tensors and the knowledge of some of their properties can be traced back to C. F. Gauss, G. F. B. Riemann, and E. B. Christoffel; their algebra and analysis were shaped into a systematic method by C. G. Ricci and T. Levi-Civita, who coined for this powerful branch of mathematics the name of absolute differential calculus.

Its chief aim is to construct and discuss relations or laws generally covariant; such, that is, as remain valid in passing from one to any other system of coordinates. This makes the subject of prime importance for differential geometry. It became the object of widespread interest after the advent of general relativity theory, in which a principal requirement is precisely such unrestricted covariance of physical laws. There are interesting applications of tensor analysis—both finite and infinite dimensional—to classical mechanics, quantum mechanics, fluid mechanics, elasticity, aeronautics, and rheology (*q.v.*).

**Definitions; Algebra of Tensors.**—Consider a continuous  $n$ -dimensional manifold or space  $S_n$  (see MANIFOLDS), whose element or point  $P(x_i)$ , is determined by assigning the values of  $n$  real independent variables or coordinates  $x_i$ . Let  $Q(x_i + dx_i)$  be another point of  $S_n$ . Then the ordered point-pair  $P, Q$  or the set of differentials  $dx_i$  is called a vector. (To begin with, the idea of size or length is foreign to this concept,  $S_n$  being thus far a nonmetrical manifold.) Let the  $x_i$  be transformed into any other system of  $n$  coordinates  $x'_i$ , the former being continuous functions of the latter with continuous derivatives  $\partial x_i / \partial x'_k$  and nonvanishing, finite Jacobian  $J = \begin{vmatrix} \partial x_1 \\ \partial x'_1 \end{vmatrix}$ ; then  $dx_i$  are transformed into

$$dx'_i = \frac{\partial x'_i}{\partial x_\alpha} dx_\alpha$$

to be summed over  $\alpha = 1$  to  $n$ , and vice versa,  $dx_i = (\partial x_i / \partial x'_\alpha) dx'_\alpha$ . (The convention will be adopted that every term in which an index occurs twice, is to be summed over all its values.) Any set of  $n$  magnitudes  $A_i$ , functions of the  $x_i$ , that are transformed by this rule, i.e., into

$$A'_i = \frac{\partial x'_i}{\partial x_\alpha} A_\alpha$$

form a contravariant tensor of rank 1, the  $A_i$  being its  $n$  components. For contravariant tensors upper indices are used, an exception being made for  $dx_i$ , the prototype of all such tensors. Next, any  $n$  magnitudes  $A_i$  that are transformed as the differentiators  $\partial / \partial x_i$ , i.e., into

$$A'_i = \frac{\partial x_\alpha}{\partial x'_i} A_\alpha$$

form a covariant tensor of rank 1, lower indices being used for such tensors. These two kinds of tensors, of rank 1, are also termed vectors; e.g., three-vectors, four-vectors (such as the rela-

tivistic four-velocity or four-potential, in space-time,  $S_4$ ), and so on, according as  $n = 3, 4, \dots$ . Similarly, any  $n^2$  magnitudes  $A_{ik}$  transformable into

$$A'_{ik} = \frac{\partial x_\alpha}{\partial x'_i} \frac{\partial x_\beta}{\partial x'_k} A_{\alpha\beta}$$

form a covariant, and any  $A^i$  transformable into

$$A'^i = \frac{\partial x'_i}{\partial x_\alpha} \frac{\partial x_\kappa}{\partial x'_\beta} A^{\alpha\beta}$$

form a contravariant tensor of rank 2. Again,  $n^2$  magnitudes  $A^{ik}$  transformable into

$$A'^{ik} = \frac{\partial x_\alpha}{\partial x'_i} \frac{\partial x'_\kappa}{\partial x_\beta} A^{\beta}_\alpha$$

are said to form a mixed tensor of rank 2, covariant in  $i$  and contravariant in  $\kappa$ . The extension to any rank is obvious. Any  $n^{r_1+r_2}$  magnitudes  $A^{i_1 \dots i_{r_1}}_{j_1 \dots j_{r_2}}$ , with  $r_1$  lower and  $r_2$  upper indices, which are transformed according to the rule

$$\left( A^{i_1 \dots i_{r_1}}_{j_1 \dots j_{r_2}} \right)' = \frac{\partial x_\alpha}{\partial x'_i} \frac{\partial x_\beta}{\partial x'_j} \dots \frac{\partial x'_\kappa}{\partial x_\alpha} \frac{\partial x'_\lambda}{\partial x_\beta} \dots A^{i_1 \dots i_{r_1}}_{j_1 \dots j_{r_2}} \quad (1)$$

form a mixed tensor of rank  $r = r_1 + r_2$ . This is the most general concept of a tensor.

A tensor of rank zero, called also a scalar, is a single function of the  $x_i$ , invariant with respect to any transformations of coordinates,  $f' = f$ .  $A_{ik}$  is symmetrical if  $A_{ik} = A_{ki}$ , and antisymmetrical or a skew tensor if  $A_{ik} = -A_{ki}$ , implying  $A_{ii} = 0$ . Similarly for  $A^i$ . Analogous definitions hold for mixed tensors, and for higher ranks. Symmetry and antisymmetry are invariant properties.

The transformed tensor components being linear homogeneous functions of the original ones, the sums of corresponding components of tensors of same rank and kind form again a tensor. Thus,  $A_i + B_i = C_i$ ,  $A_{ik} + B_{ik} = C_{ik}$ , and so on. The addends, functions of  $x_i$ , must be taken at the same point of  $S_n$ . If a tensor vanishes in one coordinate system, it will vanish also in any other. Consequently, any tensor equation, if valid in one, holds also in any other coordinate system. This is the chief reason of the importance of tensors in pure geometry and physics.

The outer product of two tensors of ranks  $r$  and  $s$  (i.e., the array of  $n^{r+s}$  products of their components) is again a tensor, of rank  $r + s$ . Thus,  $A_i B_k = C_{ik}$ ,  $A_{ik} B_\lambda = C_{i\lambda k}$ ,  $A_{ik} B^\lambda = C^\lambda_{ik}$ . The contraction, an operation of almost magical efficiency, applicable to any mixed tensor, consists in equating one of its  $r_1$  lower to one of its  $r_2$  upper indices and summing over it from 1 to  $n$ . The result is again a tensor, with  $r_1 - 1$  covariant and  $r_2 - 1$  contravariant indices; e.g., a contraction of  $A^\lambda_{ik}$  gives  $A^i_k = A_k$ , a vector;  $B^\lambda_{ik}$  contracted once becomes  $B^i_k = B_k$ , and this yields  $B_i = B$ , a scalar.

The inner product is the outer product (supposed mixed) contracted once or more. Thus, the inner product of  $A_i$ ,  $B^k$  is  $A_i B^k$ , a scalar; that of  $A_{ik}$ ,  $B^{\lambda\mu}$  gives  $A_{ik} B^{\lambda\mu} = C^{\lambda\mu}$ , a mixed tensor, and after a second contraction,  $A_{ik} B^{\lambda\mu} = C^\lambda_\mu = C$ , a scalar. Unlike  $A_i B^k$ ,  $A_{ik} B^\lambda$  is not invariant; it has no tensor character, and likewise for  $A^i B_k$ . Conversely, if  $A_i B^k$  is a scalar for any covariant vector  $A_i$ ,  $B^k$  is a contravariant vector. Similarly, if  $A_{ik} B^{\lambda\mu}$  is a scalar for any covariant  $A_{ik}$ ,  $B^{\lambda\mu}$  is contravariant. This is an efficient method of establishing the tensor character of a set of  $n, n^2, \dots$  magnitudes. (See also TENSOR ALGEBRA.)

**Differentiation.**—The differentiation of tensors with respect to the coordinates yields, in certain circumstances, further tensors. If  $f$  is a scalar function of the  $x_i$  or scalar field,  $\partial f / \partial x_i = f_i$  is a covariant vector, the gradient of  $f$  (but  $\partial^2 f / \partial x_i \partial x_k$  is not a tensor; again, if  $du$  be an invariant,  $dx_i / du$  is, but  $d^2 x_i / du^2$  is not a vector). Further, if  $A_i$  be a vector,  $B_{ik} = \partial A_i / \partial x_k - \partial A_k / \partial x_i$  is a skew tensor, the rotation of  $A_i$ . Finally, if  $A_{ik}$  be antisymmetric,  $B_{i\lambda k} = \partial A_{ik} / \partial x_\lambda + \partial A_{\lambda k} / \partial x_i - \partial A_{\lambda i} / \partial x_k$  is again such a tensor, the expansion of  $A_{ik}$ .

In what precedes only such properties of tensors were treated as are independent of any metrical considerations, the space  $S_n$

being thus far a nonmetrical, amorphous manifold. Let now its metrics be fixed by laying down the line element, a quadratic differential form with coefficients  $g_{\alpha\beta} = g_{\beta\alpha}$ , prescribed functions of the  $x$ ,

$$ds^2 = g_{\alpha\beta} dx^\alpha dx^\beta \quad (2)$$

to be considered as invariant and to serve as the measure of the (squared) size or length of the vector  $dx^\alpha$ . Then,  $dx^\alpha$  being contravariant,  $g_{\alpha\beta}$  will be covariant. Equivalently it may be said that a certain symmetrical tensor  $g_{\alpha\beta}$  is being impressed upon  $S_n$  as the fundamental or metrical tensor, converting it into a metrical manifold, a Riemannian space.

The minors  $g^{\alpha\beta}$  of  $g = |g_{\alpha\beta}|$ , divided by  $g$ , form again a symmetrical tensor, the contravariant metrical tensor, to be used along with  $g_{\alpha\beta}$ . The outer product and contraction can be used in raising and lowering tensor indices. Thus  $g^{\alpha\beta} A_\beta = A^\alpha$  and  $g_{\alpha\beta} B^\alpha = B_\beta$ .

The angle  $\theta$  between two (copunctal) vectors  $A^\alpha$  and  $B^\alpha$  is defined by the invariant  $\cos \theta = g_{\alpha\beta} A^\alpha B^\beta / AB$ ;  $A, B$  being their sizes. The unit vector  $\hat{x}_\alpha = dx^\alpha / ds$  determines, locally, a direction in  $S_n$ . The angle between two directions  $\hat{x}_\alpha, \hat{y}_\alpha$  is given by  $\cos \theta = g_{\alpha\beta} \hat{x}^\alpha \hat{y}^\beta$ .

**Integrals.**—The integral  $\int dx^1, \dots, dx^n$ , briefly  $\int dx$ , extended over a region of  $S_n$ , is transformed into  $\int J dx$ , and the determinant  $g$  into  $g' = J^2 g$ . Consequently,  $\int \sqrt{g} dx$  is an invariant metrically impressed upon that region, its size or volume (area, if  $n = 2$ ). This concept is readily extended to any submanifold of  $S_n$  characterized by  $x_i$  as functions of  $m < n$  parameters  $p_a$ , the role of metrical tensor being taken over by

$$h_{ab} = g_{\alpha\beta} (\partial x_\alpha / \partial p_a) (\partial x_\beta / \partial p_b)$$

If, by a proper choice of the coordinate system, all components  $g_{\alpha\beta}$  are reducible to constants, the metrical space  $S_n$  is Euclidean or homaloidal (flat). This is but a very special case of a Riemannian space. In general such a reduction is not possible, and  $S_n$  is non-Euclidean.

Differentiation of tensors, aided by metrics, yields an unlimited number of new tensors. The oldest of such is Riemann's set of four-index symbols of 1861. The simplest metrically differential tensor, however, was discovered in 1869 by Christoffel. This is the covariant derivative of a vector  $A_\alpha$ ,

$$A_{\alpha;\kappa} = \frac{\partial A_\alpha}{\partial x^\kappa} - \{\alpha, \lambda, \kappa\} A_\lambda \quad (3)$$

where  $\{\alpha, \lambda, \kappa\} = g^{\mu\nu} [\alpha, \mu, \kappa] = \{\kappa, \lambda, \alpha\}$  and

$$[\alpha, \mu, \kappa] = \frac{1}{2} (\partial g_{\mu\alpha} / \partial x^\kappa + \partial g_{\mu\kappa} / \partial x^\alpha - \partial g_{\alpha\kappa} / \partial x^\mu)$$

are Christoffel's symbols (not forming a tensor). Again,

$$B^{\lambda;\kappa} = \partial B^\lambda / \partial x^\kappa + \{\alpha, \kappa, \lambda\} B^\alpha$$

is a mixed tensor.

$$C^{\alpha;\kappa}_\lambda = \partial C^{\alpha\kappa} / \partial x^\lambda + \{\lambda, \alpha, \iota\} C^{\alpha\kappa}_\iota + \{\lambda, \kappa, \iota\} C^{\alpha\iota}_\lambda \quad (4)$$

$$C_{\alpha\lambda;\kappa} = \partial C_{\alpha\lambda} / \partial x^\kappa - \{\alpha, \kappa, \iota\} C_{\iota\lambda} - \{\lambda, \kappa, \iota\} C_{\alpha\iota} \quad (5)$$

are the covariant derivatives of  $C^{\alpha\kappa}$  and  $C_{\alpha\lambda}$ . The covariant derivative of  $g_{\alpha\beta}$  itself vanishes identically. Noteworthy for their applications are

$$A^\alpha = \text{Div}(A^\alpha) = \frac{1}{\sqrt{g}} \frac{\partial}{\partial x^\alpha} (\sqrt{g} A^\alpha) \text{ and } \text{div}(A^\alpha) = \frac{1}{\sqrt{g}} \frac{\partial}{\partial x^\alpha} (\sqrt{g} A^\alpha),$$

the vector divergence of a skew  $A^{\alpha\kappa}$  and the scalar divergence of  $A^\alpha$ ; e.g., one group of James Clerk Maxwell's equations is represented by  $\text{Div}(F^{\alpha\kappa}) = C^\alpha$ , where  $C^\alpha$  is the four-current and  $F^{\alpha\kappa}$  the electromagnetic skew tensor (six vector); the second group being expressed by equating to zero the expansion of  $F_{\alpha\kappa} = g_{\alpha\beta} g_{\kappa\gamma} F^{\beta\gamma}$ .

**Geodesics, Null Lines.**—The most characteristic curves of the metrical  $S_n$  are its null or minimal lines,  $ds = 0$ , and "shortest" curves or geodesics defined by  $\delta \int ds = 0$ , with fixed terminals. The equations of a geodesic are

$$\ddot{x}^\alpha + \{\alpha\beta, \gamma\} \dot{x}^\beta \dot{x}^\gamma = 0 \quad (6)$$

where  $\dot{x} = dx/ds$ . They determine, e.g., in the case of space-time, the motion of a free particle in the metrical, and gravitational, field  $g_{\alpha\beta}$ . The null lines are imaginary or real according as equation (2) is a definite or nondefinite form. The former is the case of spaces proper as contemplated by the pure geometer, and the

latter that of space-time with one positive and three negative  $g_{\alpha\beta}$ . The null lines of space-time represent light propagation. The definiteness or nondefiniteness of the quadratic form and its index of inertia (number of negative  $g_{\alpha\beta}$  terms) are invariant properties.

**Parallel Displacement of Vectors.**—A fruitful contribution to tensor analysis due to Levi-Civita is the concept of parallel displacement of a vector with respect to a curve. The metrical  $S_n$  can in general be imagined as imbedded locally in a Euclidean space  $E$  of  $\frac{1}{2}n(n+1)$  dimensions. Levi-Civita defined parallel displacement in  $S_n$  as a consequence of a parallel displacement in  $E$ . In spite of the ultraspatial construction, parallelism is intrinsic, expressible by the  $S_n$  metrics alone.

If  $x_i = f_i(s)$  are the parametric equations of any chosen curve  $C$ , then the differential equations along  $C$

$$\frac{dA^\alpha}{ds} + \{\alpha\beta, \gamma\} A^\beta \dot{x}^\gamma = 0 \quad (7)$$

with the initial vector  $A^\alpha(s_0) = A^\alpha_0$  determine uniquely a contravariant vector  $A^\alpha$  at each point of the curve. The vector  $A^\alpha$  at the point corresponding to  $s = s$  is said to be obtained by a parallel displacement of the vector  $A^\alpha_0$  with respect to the given curve  $C$ , and is said to be parallel to  $A^\alpha_0$ . Any two vectors generated as above, one at each point, are parallel with respect to  $C$ .

Let it be required to construct a curve whose tangents follow from each other by parallel displacement along the curve itself. This gives the equations (6), so that the curve is a geodesic. The latter is thus throughout "parallel to itself"—an interesting generalization of the property of Euclidean straights. Accordingly, a vector transferred along a geodesic remains equally inclined to it.

If a vector  $X^\alpha$  be carried by parallel displacement along two different paths  $a, b$  from  $O$  to  $O'$ , the two vectors at  $O'$ , equal in size, generally differ in direction. One is parallel to  $X^\alpha$  via  $a$ , the other via  $b$ . In short, parallelism depends on the route of transfer or is nonintegrable (unless  $S_n$  is essentially Euclidean). Thus also, if the vector be carried around a circuit, it returns at  $O$  with its direction changed.

The covariant derivative of the vector is the tensor  $X_{\alpha;\beta}$ . Its covariant derivative  $X_{\alpha;\beta;\gamma}$  is not symmetric in  $\alpha$  and  $\beta$ . A straightforward calculation shows that

$$X_{\alpha;\beta;\gamma} - X_{\alpha;\gamma;\beta} = R^\alpha_{\gamma\beta\delta} X^\delta \quad (8)$$

where

$$R^\alpha_{\gamma\beta\delta} = \frac{\partial}{\partial x^\alpha} \{\delta, \beta, \gamma\} - \frac{\partial}{\partial x^\beta} \{\delta, \alpha, \gamma\} + \{\alpha\gamma, \kappa\} \{\delta, \beta, \kappa\} - \{\beta\gamma, \kappa\} \{\delta, \alpha, \kappa\} \quad (9)$$

This is the Riemann-Christoffel or curvature tensor whose vanishing is the necessary and sufficient condition for the reducibility of  $g_{\alpha\beta}$  to a constant tensor, or the criterion of a homaloidal (Euclidean) space.

**Riemann's Four-index Symbols and Curvature.**—Riemann's own set of four-index symbols is the covariant tensor  $(\mu, \lambda, \kappa) = R_{\mu\lambda\kappa} = g_{\mu\alpha} R^\alpha_{\lambda\kappa}$ . Conversely,  $R^\alpha_{\lambda\kappa} = g^{\mu\alpha} (\mu, \lambda, \kappa)$ . Like equation (9), the symbols are antisymmetric in  $\kappa, \lambda$ . Three more linear relations hold between them. This reduces the number of independent symbols to  $\frac{1}{2}n^2(n^2 - 1)$ ; e.g., six for a three-space, twenty for an  $S_4$ , and but one for a surface, say (12, 12). This symbol divided by  $g$  is a scalar of the surface, its Gaussian curvature  $K$ . If a vector undergoes parallel displacement around a circuit on a surface, it returns with its direction changed by an amount equal to  $\int K d\sigma$ , the Gaussian curvature of the surface integrated over the surface area enclosed by the circuit. As a consequence, the excess (over  $\pi$ ) of the angle sum in any geodesic triangle is  $\int K d\sigma$ , a famous theorem due to Gauss. (See also DIFFERENTIAL GEOMETRY.)

In the case of three or more dimensions the curvature properties can no longer be expressed by a single magnitude, but require for their description the knowledge of the whole curvature tensor or the associated Riemann symbols. The concept of Gaussian curvature is now replaced by that of Riemannian curvature, i.e., at any point  $O(x)$  of  $S_n$ , the set of Gaussian curvatures  $K$  of

geodesic surfaces of all possible orientations laid through  $O$ . If  $h_{\alpha\beta}$  be the metrical tensor of such a surface as submanifold, then  $K = \frac{1}{h} (12, 12)_{hh}$ , the symbol to be calculated with  $h_{\alpha\beta}$ . This and the determinant  $h$  can be expressed in terms of the tensor  $g_{\alpha\beta}$  of the manifold and the vector pair,  $\xi, \eta$ , fixing the orientation. The result is

$$K = \frac{(\lambda\kappa, \lambda\mu)\xi^\alpha\eta^\beta\xi^\lambda\eta^\mu}{(g_{\lambda\alpha}g_{\mu\beta} - g_{\mu\alpha}g_{\lambda\beta})\xi^\alpha\eta^\beta\xi^\lambda\eta^\mu} \quad (10)$$

In general,  $K$  will depend on position and on orientation. In other words, with regard to curvature,  $S_n$  may be nonhomogeneous as well as anisotropic (e.g., space-time within or around matter); but if  $K$  is everywhere isotropic, it is also constant throughout  $S_n$  (Schur's theorem). By equation (10) the necessary and sufficient condition for isotropy of Riemannian curvature becomes  $(\lambda, \kappa) = K(g_{\lambda\alpha}g_{\mu\beta} - g_{\mu\alpha}g_{\lambda\beta})$  or  $R^\alpha{}_{\alpha\lambda\lambda} = K(\delta^\alpha{}_\lambda g_\lambda - \delta^\alpha{}_\lambda g_\lambda)$  with constant  $K$ . See also RIEMANNIAN GEOMETRY.

Brillouin, *Tensors in Mechanics and Elasticity*, trans. by R. O. Brennan (1964). (L. SN.; A. D. ML.; X.)

**TENTERDEN, CHARLES ABBOTT**, 1st BARON (1762–1832), lord chief justice of England, was born at Canterbury on Oct. 7, 1762, the son of a hairdresser. He was educated at King's School, Canterbury, and Corpus Christi College, Oxford, and entered the Middle Temple in 1787. For several years he practised as a special pleader under the bar, and was finally called at the Inner Temple in 1796. He joined the Oxford circuit and made rapid headway. In 1801 he was appointed recorder of Oxford. In 1802 his influential *Law Relative to Merchant Ships and Seamen* appeared. In 1808 he refused a seat on the bench; this, however, he accepted in 1816, being made a judge of the court of common pleas.

On the resignation of Lord Ellenborough in 1818 he was promoted to the chief justiceship of the king's bench, and presided over several important state trials, notably that of Arthur Thistlewood (*q.v.*) and the Cato Street conspirators (1820). He was raised to the peerage in 1827 as Baron Tenterden of Hendon. Never a great lawyer, Tenterden made his way by steady hard work. He was an uncompromising Tory and had no sympathy with the reform of the criminal law carried out by Sir Samuel Romilly. He strongly opposed the Catholic Relief Bill and the Reform Bill. Tenterden died on Nov. 4, 1832.

See E. Foss, *The Judges of England* (1870).

**TENTERDEN**, a municipal borough in the Ashford parliamentary division of Kent, Eng., 19 mi. (31 km.) SSE of Maidstone. Pop. (1961) 4,948. An agricultural centre, it lies on a hill above the Newmill Channel, a tributary of the Rother, whose fertile valley (Rother levels) was once an estuary; in the 18th century the sea was within two miles of Tenterden, which was a limb of the Cinque Port of Rye. St. Mildred's Church is mainly Early English, and its Perpendicular tower is associated with the legend of Goodwin Sands, which tells how the abbot of St. Augustine's, Canterbury, diverted funds for repairing the sea wall protecting Earl Godwin's island in order to build the steeple; in 1099 an inundation took place, and "Tenterden steeple was the cause of the Goodwin Sands." The nearby church of High Halden has an octagonal wooden tower with a belfry of wooden tiles (shingles). In 1449 Tenterden was incorporated with Rye and granted a charter which did not function until 1463. In 1600 it was re-incorporated under the "Mayor, Jurats and Commons" as the town and hundred of Tenterden, the members of the corporation ranking as barons of the Cinque Ports. In this capacity they had the privilege of attending the court of Sheppey to elect the lord wardens.

Small Hythe Place, 2 mi. S, is maintained by the National Trust as the Ellen Terry Memorial Museum, having been her residence for 25 years.

**TENURE, JUDICIAL**, refers to the length and conditions of office for judges. Essential to the maintenance of an independent judiciary is a tenure of office adequate to ensure freedom

from political and economic pressure. The truth of this proposition was recognized by the authors of the constitution of the United States, and all judges of federal courts created pursuant to art. iii hold office during "good behaviour"; i.e., for life. Most other federal judges are granted similar tenure by statute. Thus, though a federal judge is eligible to retire at full salary after a given number of years of service, he may not be compelled to surrender his office except for misbehaviour. Similar constitutional and statutory protection is afforded judicial compensation, which may not be reduced during the tenure of an incumbent. Both the federal and English judicial systems have demonstrated the value of and necessity for such extended tenure of office, even at the occasional price of retaining a superannuated or less competent judge.

The state court systems in the U.S. have lagged far behind, with the result that political influence is rife in the administration of justice in the states. Only two states, Massachusetts and New Hampshire, have absolute life tenure, but Rhode Island has it in fact if not in law. The terms of judges in other state courts vary from 2 years in the Vermont trial and appellate courts to 21 years in the supreme court of Pennsylvania. Life tenure is usually associated with a judiciary appointed by the executive, as in the federal and English systems. Where the judiciary is elected, terms of office have been severely restricted as part of the Jacksonian notion of democratic control of the courts. Most reform movements do not, however, recommend life tenure. They seek a system whereby an incumbent is required to run for re-election on the basis of his record, giving the electorate a choice of retention or rejection. This method of tenure, generally known as the Missouri plan, has the support of the American Bar association, among others, although there is no evidence to support the proposition that the Missouri plan has any advantages over the life tenure system in effect in the federal courts. (P. B. K.)

**England**.—Until the end of the 17th century most judges were appointed *durante bene placito* ("during the royal pleasure"); and there were many instances of judges being dismissed. When the Act of Settlement, 1701, s. 3, came into force in 1714, judges were appointed *quamdiu se bene gesserint* ("during good behaviour"), and they were removable (and probably removable only) upon the address of both houses of parliament. The Judicature act, 1925, s. 12, preserves this position, which applies to all judges of the high court and court of appeal; and by ss. 13–15 their salaries and pensions were established and charged on the consolidated fund, so that they are not subject to the annual vote of parliament. However, these provisions are subject to the omnipotence of parliament, and statute has reduced and, more recently, increased the salaries and pensions. All judges appointed since the Judicial Pensions act, 1959, must retire when they become 75 years old. A county court judge is removable by the lord chancellor for "inability or misbehaviour," and he must retire when he is 72 years old, subject to a possible extension to 75 (County Courts act, 1959, s. 8). The lord chancellor similarly has power to remove any justice of the peace, and many other lower judicial officers. The independence of English judges is thus secured less by formal provisions of law than by the public opposition likely to be aroused by any improper attempt to coerce them. (R. E. MY.)

**TENZING NORGAY** (?1914– ), Sherpa mountaineer, the first man, with Sir Edmund Hillary, to set foot on the summit of Everest (29,028 ft.), was born in 1914 (he believes), in Solo Khumbu, the district south of Everest which is inhabited by the Sherpas. He was named Namgyal Wangdi. At the age of 18 he migrated to Darjeeling, where he lived by carrying loads, and in 1935 and 1936 went as porter on Everest expeditions. In 1938 he carried to Camp VI (27,200 ft.). After World War II he set up as sirdar, or organizer of porters, and accompanied a number of expeditions. In 1952 the Swiss made two attempts on the southern route up Everest, on both of which Tenzing was sirdar. He went as sirdar of the British expedition in 1953 and formed the second summit pair with Hillary. From a tent at 27,900 ft. on the southeastern ridge they reached the summit at 11:30 A.M. on May 29. After this achievement Tenzing received many honours

and was regarded with religious awe by many Nepalese and Indians.

See Tenzing Norgay, *Man of Everest*, as told to James Ramsey Ullman (1955). (C. W. F. N.)

**TEPEXPAN MAN** is one of the most important skeletal remains of early American Indians because of the good data concerning its geological position and contemporary faunal remains. It was found in 1947 by Helmut de Terra and associates near the village of Tepexpan in the Valley of Mexico. The skeleton, once identified as male, seems to be that of a female no older than 30 years when she died, and about 1.5 m. (not quite 5 ft.) tall. The skull is large, with an endocranial capacity of 1,540 cc. The cranial index is 79.89 (breadth/length  $\times 100$ ).

Most other crania of early American Indians, such as those found at Lagoa Santa, Braz., Punin, Ecuador, and Midland, Tex., have been narrower, with an index below 75. There is always some variation within a group, and this relatively broader-headed individual could easily have been a member of a group whose mean cranial index was much less. Some early skeletal remains found later at Tehuacán Valley come close to Tepexpan chronological estimates.

The skeleton lay face down and flexed in silt deposits of the El Risco sand, a lake facies of the Upper Becerra formation. This silt suggests a moist period and was overlain by caliche deposits suggesting a dry climatic period. Geologically these deposits permitted an estimate of 11,000 to 12,000 years ago for the silt. A radiocarbon age of  $11,003 \pm 500$  years was derived from a peat specimen belonging to the same level as that of the skeleton.

A number of fossil elephant remains and an obsidian flake were found in related deposits. These, and bones of horse, bison, pocket gopher, and deer indicate a habitat with more luxuriant vegetation than in modern times and suggest that this man may have been a big-game hunter.

Cook, "New Evidence of Antiquity of Tepexpan . . ." *Southwestern Journal of Anthropology*, vol. 15 (1959); S. Genovés, "Revaluation of Age, Stature and Sex of the Tepexpan Remains, Mexico," *American Journal of Physical Anthropology*, vol. 18 (1960). (W. S. Lx.)

**TEPLICE**, a town of the North Bohemian region of Czechoslovakia, known for its hot springs, lies on a rocky spur below the Ore Mountains (Erzgebirge), 56 mi. (90 km.) NNW of Prague. Pop. (1961) 44,136. At Milešovka Mountain (south-east) is the important observatory maintained by the Czechoslovak Academy of Sciences. Teplice is a rail and road junction.

Archaeological evidence suggests that the springs were known to the Romans, and they are mentioned in Bohemian legend (8th century). In 1156 a convent was founded there by Judith, queen of Bohemia; two ancient towers in the grounds of the 18th-century Clary-Aldringen Palace are thought to be remains of this foundation. The belief that gunshot wounds could be alleviated by the Teplice waters led to the Austrian, Prussian, and Saxon authorities maintaining their own spa establishments in the 19th century for disabled men.

The proximity of lignite deposits caused industrial development in and around Teplice in the 19th century (mining, glass, pottery, timber, and engineering). In 1879 flooding of the lignite mines by the underground springs damaged industrial and spa activities alike, and later, Teplice was overshadowed by Karlovy Vary (formerly Carlsbad) and other spas in West Bohemia. After World War II it prospered again both industrially and as a cure resort. (H. G. S.)

**TEQUILA**, a variety of mescal (*q.v.*), the Mexican brandy, distinguished by its place of production: the states of Guanajuato and Jalisco, especially around the town of Tequila. The roasted crowns of several species of *Agave* provide the mash for fermentation and distillation. *Tequila almendrado* is almond flavoured. (L. Ka.)

**TERAI** (TARAI) (*i.e.*, "moist land"), the name given to the strip of formerly marshy land stretching parallel to the lower ranges of the Himalayas in northern India. It extends roughly from the Jumna (Yamuna) River on the west to the Brahma-

putra on the east, and a large portion of it lies within Nepal. The name is also used officially for a subdivision of Nainital District in Uttar Pradesh. At its northern edge, where the often riverless forest tract of the bhabar (coarse gravel deposits) ends, a series of springs burst from the surface, and these, increasing and uniting in their progress, form the numerous streams that intersect the Terai and were responsible for its marshy character. The Gogra (Ghaghara) is the great river of the Terai proper and is navigable from the Himalayan foothills.

For long the Terai was the haunt of elephants, tigers, leopards, and many other wild animals. It was notoriously unhealthy and only sparsely inhabited by tribes seemingly immune to malaria. Gradually agriculturalists from the adjoining plains to the south penetrated the Terai, draining it, training the streams, and cultivating the land so that comparatively little of the Terai now remains. The Terai is known in Bengal (both West Bengal and the northern part of East Pakistan) as *duars*. (L. D. S.)

**TERAMO**, chief town of Teramo Province, Abruzzi e Molise region, Italy, and the seat of a bishop, lies between the Tordino and Vezzola rivers 15 mi. (24 km.) from the Adriatic and from the Gran Sasso d'Italia. Pop. (1961) 40,559. Remains include the ruined Roman amphitheatre; a 12th–14th-century cathedral, with a square campanile, in which is a portal of 1332; and the Church of S. Agostino, containing a 15th-century polyptych. There is an astronomical observatory 2 mi. (3 km.) from the town. Teramo is linked to the coastal resort of Giulianova on the Milan-Brindisi railway. Agriculture, mainly cereal production, is the main occupation. The town is the successor of Interamna (Interamna) of the tribe of the Praetuttii. Invaded by the Goths and Lombards, and rebuilt by Bishop Guido (1155, it followed the fortunes of the kingdom of Naples.

TERAMO PROVINCE, with an area of 752 sq.mi. (1,949 sq.km.) and a population (1961) of 238,303, is mainly engaged in agriculture. Traditional occupations are the making of majolica and terra cotta, with an art school at Castelli. There is a Gothic cathedral at Atri, a 12th-century Franciscan shrine at Isola del Gran Sasso d'Italia, and a Bourbon fortress at Civitella del Tronto. (M. T. A. N.)

**TERAPHIM**, a Hebrew word, found only in the plural of uncertain etymology, referring apparently to some sort of idol. In Gen. 31, which tells the story of Rachel's stealing her father's teraphim (variously translated "images," "household gods," "gods" in English Bibles), they are clearly plural, small, and portable but details as to their precise configuration, etc., are lacking. From I Sam. 19, which describes Michal's use of the teraphim to save David from Saul, it appears that the teraphim was singular and man-sized. The passage further suggests that in the early monarchical period (late 11th century B.C.) a regular place in every household was still reserved for the teraphim; while in the 8th century, Hosea (3:4) speaks of "ephod and teraphim" as essential elements in the national worship. Later the teraphim, like other pre-Israelite religious elements, were banned by the prophets. The meaning of the story in Gen. 35:2–4 ("strange gods" or "foreign gods" in English Bibles) clearly is that the employment of teraphim was given up by Israel in order that Yahweh alone might be served at Bethel. In Judges and Hosea the teraphim are closely associated with the ephod (*q.v.*); both are mentioned in connection with divination (*cf.* II Kings 23:24; Ezek. 21:21; Zech. 10:2). In view of Ezek. 21:21 and Hosea 3:4, it is difficult to suppose that the teraphim were purely household idols.

**TERATOLOGY**, the study of abnormalities and monstrosities in plants and animals. See MONSTER.

**TERBIUM** (symbol Tb) is a silver-white metallic element of the rare-earth group, atomic number 65 and atomic weight 158.924. The only isotope occurring in ores is  $Tb^{159}$  which is stable; radioactive  $Tb^{160}$  (half-life 73 days) is used as an indicator in the study of coprecipitation processes. The element was discovered by C. G. Mosander in 1843 in a heavy rare-earth fraction called yttria, but its existence was not confirmed for at least 30 years and pure compounds were not prepared until 1905. The name terbium was derived from the town of Ytterby in Sweden. Terbium occurs in many rare-earth minerals such as gadolinite,

renotime, euxenite, and samarskite; it is also found in the products of nuclear fission. However, it is usually obtained as a by-product from the monazite sands, a source of thorium. Ion-exchange techniques are utilized for commercial production.

Terbium is one of three rare earths that have an oxidation state of plus four (see CERIUM; PRASEODYMIUM). The brown oxide prepared by air ignition has the approximate formula  $Tb_4O_7$ ;  $TbO_2$  is obtained by a more drastic oxidation procedure; and  $TbF_4$  is prepared by use of elemental fluorine. In all other salts and in solution terbium is trivalent with an ionic radius of 0.923 Å and behaves as a typical rare earth. The thermal neutron cross section is 55 barns. Its solutions are colourless and have discrete absorption lines in the ultraviolet region of the spectrum which are of use for quantitative analysis. Because of unpaired 4f electrons, the trivalent terbium ion is very strongly paramagnetic. The metal is prepared in a highly pure form by thermoreduction of the anhydrous fluoride with calcium metal. It is slowly oxidized by air at room temperatures and by cold water. The melting point of the metal is 1,356° C, its density is 8.253 g. per cm<sup>3</sup> for the hexagonal close-packed structure; it is ferromagnetic below -68° C (see also RARE EARTHS). (Ld. B. A.)

**TERBORCH** (TER BORCH), **GERARD** (1617-1681), Dutch painter, who developed his own distinctive type of interior genre, in which he depicted with grace and fidelity the atmosphere of well-to-do middle-class life, was born at Zwolle. His father had been an artist and had visited Rome, but from 1621 was employed as a tax collector. Surviving drawings made by the young Terborch in 1625 and 1626 are proudly inscribed and dated by his father. In 1632 Gerard was in Amsterdam and in 1634 he was a pupil of Pieter Molyn (Molijn) in Haarlem. He visited England in 1635, Rome in 1640, and from 1646 spent two or three years in Münster, Westphalia, where the peace congress was in session. The masterpiece of this period is the "Peace of Münster" (National Gallery, London), of 1648, which portrays the delegates of Holland and of Spain assembled to sign the peace treaty. After a stay in Madrid he had finally returned to his own country by the end of 1650. In 1654 he was married in Deventer, where he settled for the remainder of his life, dying there on Dec. 8, 1681.

BY COURTESY OF THE EUNSTHISTORISCHES MUSEUM, VIENNA  
"WOMAN PEELING APPLES" BY GERARD TERBORCH, 1661

Terborch's works consist almost equally of portraits and genre pieces. His characteristically delicate technique can be appreciated in the portraits, which are painted on a small, almost miniature scale, though many of them are full-lengths. In colour they tend to be subdued, due largely to the sober costume of the times, but by subtlety of tonal gradations and mastery in rendering diverse surface textures he was able to achieve an extraordinary richness of effect. His superb colour sense appears to greater advantage in genre subjects, though always employed with masterly restraint. In his earlier years he painted many guardroom subjects in the manner of Pieter Codde and Willem Duyster, but later, from about the time when he finally settled in Holland, he painted calm, exquisitely drawn groups, posed easily and naturally against shadowy backgrounds, and imbued with an almost aristocratic elegance that is unique among Dutch painters of his time. Among many fine examples of Terborch's art may be mentioned "The Letter" (Buckingham Palace, London), "The Concert" (Berlin), "Fatherly Advice" (Amsterdam), and "Woman Peeling Apples" (Vienna).

See E. Plietzsch, *Gerard Ter Borch* (1944).

(R. E. W. J.)

**TERCEIRA**, an island in the Atlantic Ocean, belonging to Portugal and forming part of the Azores (*q.v.*) archipelago. Pop. (1960) 72,485; area 153 sq.mi. (397 sq.km.). Terceira ("the third") was so called because it was the third island of the archi-

pelago to be discovered by the Portuguese. The commercial importance of Angra do Heroísmo, the chief town and port, has much increased owing to the NATO military air base at Lajes, maintained by the Portuguese Air Force. Since World War II the United States Air Force has used it as a military transport station. Praia da Vitória, with its wide bay protected by a breakwater, handles military supplies for the air base. (J. Ao.)

**TEREDO**, a genus of highly specialized wormlike bivalve mollusks (*q.v.*) belonging to the family Terebridae, commonly known as shipworms, pileworms, teredos, or teredines. They are related to the piddocks (*q.v.*) and to the soft-shelled clam, *Mya*. There are about 10 genera, the best known being *Teredo* and *Bankia*, and perhaps 100 species. They are worldwide in distribution, generally living in marine or brackish water, though a few species are found in fresh water. They can be extremely destructive to wooden vessels or waterfront installations and have been of great concern to maritime peoples since earliest times. They have been called "terminals of the sea" because the damage they do is not readily seen; the outer surface of the wood may look undamaged and yet the interior may be completely riddled.

Teredos are known to have existed as far back as the Jurassic period. Before the advent of man, they lived in fallen trees that were carried into the sea by rivers or that had fallen along the shores; they were thus important in the reduction of the wood to the elements. It was only when man began building wooden ships and wharves that teredos became pests.

**General Features.**—Teredos may be compared to a soft-shelled clam, the body of which has been stretched out so that the highly modified shell covers only a very small portion of the anterior end of the animal. The body is wormlike and, unlike other bivalves, most of the vital organs are posterior to the posterior adductor muscle. The separate siphons, used in feeding and respiration, are relatively short and protrude from the minute opening of the burrow into the water. The incurrent siphon carries water and food in; the excurrent carries wastes out. The valves of the shell are nearly hemispherical, with a deep right-angled notch in the ventral half of the anterior margin. Parallel with the edges of the notch, the outer surface of each valve is marked with fine ridges that when magnified appear as rows of minute teeth like those of a file. The large muscular foot, which protrudes through the anterior gape, acts as a suction disc to hold the valves tightly against the anterior end of the burrow when the teredo is actively boring. As in the piddocks, the anterior adductor muscle has migrated to the outside of the shell. Posteriorly, a large lobe or auricle is produced for the attachment of the powerful posterior adductor muscle. At the umbos (prominences at the hinges) and on the ventral margins of the valves opposite to them are large rounded knobs or condyles on which the valves rock. The large foot muscles are attached to the apophyses, two calcareous "arms" that protrude from under the umbos. The large posterior adductor muscle supplies the force for boring, and the shell is the tool with which it works. When actively boring, the teredo contracts the anterior adductor muscle, bringing the anterior end of the valves together and spreading the posterior end. The foot is firmly attached to the end of the burrow and the foot muscles contracted, drawing the valves forward and bringing the denticles hard against the wood. Then, the forceful contraction of the posterior adductor muscle spreads the valves anteriorly and the filelike denticles scrape against the wood, rasping off fine particles. The rhythmic contraction and relaxation of the anterior and posterior adductor muscles may be repeated many times before the animal rests. The surface of the foot and the margins of the mantle are covered with cilia that carry the fine particles of wood into the mantle cavity and to the mouth.

At the posterior end of the stomach is a large sac or caecum usually filled with wood particles. Digestive enzymes in the stomach and caecum can reduce the wood sugars to a usable form, and provides some of the food of the teredo. Teredos also feed on microscopic plants and animals carried into the mantle cavity through the incurrent siphon.

When shipworms are undisturbed, the siphons can be seen extending from the minute opening at the surface of the wood and

(ABOVE) CHARLES E. LANE, (BELOW) A. J. MCQUIRE

(Above) A one-inch plank infested by shipworms. The larvae bore into the wood through tiny holes on the surface (the broken edge shows the internal damage inflicted); (below) *Bankia australis*, photographed by X ray, inside a board submerged for six months

waving about gently in the water. If they are disturbed, however, or conditions become adverse, the siphons are drawn into the burrow and the opening is plugged by a pair of paddle-shaped plates (pallets). The pallets effectively protect the animal against predators as well as adverse conditions such as reduced salinity, pollution, or silting. Inactive shipworms may remain for extended periods of time with the siphons retracted.

The breeding habits of the various members of the family vary considerably. In some species, the eggs and sperm are emitted into the water, where fertilization takes place. In others, fertilization is internal, but the eggs are extruded into the water at an early stage in development. In still others, the gills serve as a brood pouch where the young are held until development is nearly complete. All species have a free swimming period, and it is by this means that new timber is invaded. Eventually, the embryo shipworm must settle on wood or die. It first attaches itself by a single byssus thread; then, with the edges of its valves, it scrapes together loose wood fibres with which it makes a small cone to protect itself during the period of change from a typical embryonic bivalve to a highly specialized boring animal. The shell changes radically in shape, and the apophyses and pallets develop at this time. Once these changes are complete, active boring begins. As the animal grows, the burrow is lengthened and gradually widened. Although the entrance hole remains nearly microscopic, the anterior end of the burrow may reach an inch or more in diameter as the animal grows. In temperate seas teredos usually attain only a few inches in length, but in tropical seas some species may reach six feet. Growth is usually rapid; the young at the time of attachment are about .25 mm. but they may reach over 100 mm. in length within a month.

**Control Measures.**—The ships of Archimedes of Syracuse were protected by a sheathing of lead. Copper sheathing was first used by the British in 1758. Although it was expensive, because it wore thin and had to be constantly replaced, copper gave

complete protection both from borers and fouling organisms such as barnacles. In the days of the clipper ships, nearly all vessels sailing in tropical seas were sheathed with copper, but it was found necessary to insulate the copper from the rudder iron since these two elements tend to react corrosively. With the advent of metal ships the problem of teredos ended so far as commercial shipping was concerned, but it is still a problem for the smaller fishing or pleasure boats and specialized ships such as mine sweepers, which are made of wood.

So far as waterfront installations are concerned, teredos are still a significant though decreasing problem as more and more wharves and piers are being constructed of steel and concrete. The Dutch were the first to be greatly concerned with the depredations of zeeworms, for the very existence of much of their country depended on the maintenance of a series of dikes partly constructed of wood. As a result of a severe infestation of the dikes, there appeared in 1733 an important book on teredos written by Godfrey Sellius. (It was he who showed that shipworms were mollusks rather than worms.) Of the more recent attacks, the most famous was the invasion of shipworms in San Francisco Bay during 1917–21, when destruction of wharves and jetties was estimated to have cost over \$25,000,000.

Since that time there has been an almost continuous series of investigations into the teredo problem. Numerous techniques have been developed for the protection of wood against teredo. Some are quite effective; however, many are far too involved and too expensive to be practicable on a large scale. An old but still most practical method of protection is to treat wooden wharves with coal tar creosote solution. If a high quality creosote is properly applied and allowed to impregnate the piling, the wood will give long service. The effect seems to be largely mechanical: the creosote clogs the denticles of the young teredo and renders the rasping tool ineffective. As the creosote leaches from the outer surface of the pile it is replaced by that within.

The owner of a wooden boat has a choice of a large number of available paints and coatings. However, successful and lasting protection can only be achieved if the coating is kept intact. The slightest abrasion or wearing off of the paint will allow the teredos to enter, and once inside, destruction is rapid. The most effective paints are soft and have a copper base giving protection against both boring and fouling organisms. Fibre glass coatings are used to some extent on small boats and the glue used in making marine plywood has been developed as a deterrent to borers.

Despite all the advances made in teredo control, there is still no permanent protection against them, and constant checks must be made on any wood in contact with seawater.

**TEREK**, a river of the U.S.S.R., one of the main streams draining northward from the Caucasus. It is 373 mi. (600 km.) long and drains a basin of 16,873 sq mi. (43,700 sq.km.). It rises from the glaciers of Gora (Mt.) Kazbek in the main Caucasus range and cuts its way northward through the series of ranges in spectacular gorges, between which are mountain basins. Emerging from the foothills, it turns eastward between the Caucasus and the Nogay steppe and enters the Caspian Sea by a complex delta. Its chief tributaries are the Ardon, Uruk, and Malka on the left and the Sunzha on the right. The average annual discharge is 12,360 cu.ft. (350 cu.m.) per sec., but much water is drawn off for irrigation. Freezing takes place only in the most severe winters. For much of the 19th century the Terek represented the frontier of Russian settlement in the Caucasus, and the Cossack fortified villages then established on its northern bank formed the setting of Tolstoi's novel *The Cossacks*. (R. A. F.)

**TERENCE** (PUBLIUS TERENTIUS AFR) (c. 185?–c. 159 B.C.), was, after Plautus, the greatest Roman writer of comedy. Information concerning his life comes from the account by Suetonius (fl. and century A.D.), prefaced to Aelius Donatus' 4th-century commentary, which quotes the (often conflicting) statements of earlier writers. It relates that he was born in Carthage and came to Rome as a slave in the house of Terentius Lucanus, a senator, by whom he was educated and set free. He won the friendship of certain noble Romans; the prevailing view included among these the younger Scipio and Laelius, who were even said to have helped him in his work. His first play was the *Andria*, which at the order of the aediles he read to the elderly comic dramatist Caecilius (who died 168 B.C.). After the production of the last of his plays, in his 25th year, he went to the east; from this voyage he did not return.

This account is partly contradictory and wholly unreliable. That Terence had noble friends is indeed clear from his own prologues. From the *didascaliae* (prefaces to the plays), confused as they are, it appears that his six plays were produced between 166 and 160 B.C. Their order is uncertain; but it is agreed that the first was the *Andria* ("Woman from Andros"), translated from the *Andria* of Menander.

The scene, as in all Terence's plays, is in Athens. Simo wishes his son Pamphilus to marry Philumena, daughter of their neighbour Chremes. But Pamphilus has secretly formed a liaison with Glycerium, a poor but modest girl who has recently come to Athens from Andros with her supposed sister Chrysis, now dead. The lovers are saved by the discovery that Glycerium is herself the long-lost daughter of Chremes. Terence, in translating Menander's play, made certain alterations (attested by Donatus); he changed the opening monologue into a dialogue, and he added two characters, Charinus, who is in love with Philumena, and his servant Byrrhia. The fact that he had made alterations became known to a rival of Terence, an elderly dramatist named Luscius Lanuvinus. He protested that a translator had no right to "spoil" (*contaminare*) his original. To defend himself, Terence was forced to write a prologue, in which he asserted that all he had done was to borrow suitable material from a very similar play by Menander, the *Perinthia* ("Woman from Perinthus"). He further claimed that he had merely followed the example of his predecessors, Naevius, Plautus and Ennius, whose "carelessness" he would rather imitate than the *obscura diligentia* of his critic. It seems reasonable to suppose that Terence is not here defending himself merely against the charge of borrowing material from a second Greek source; that is in fact the procedure of which he boasts, and which he intends to repeat. His enemy seems to have retorted "In that case you have spoiled not one Greek play but two"; a charge to which he replies in the prologue to the *Heautontimorumenos* ("Self-Tormentor"). He repeated this procedure in the *Eunuchus*, adding (he says) to Menander's *Eunuchus* two characters from the *Colax* ("Flatterer") also by Menander. Again in the *Adelphi* ("Brothers") he says that he has inserted a scene from the *Synapthnescontes* ("Dying Together") of Diphilus, "carelessly" omitted by Plautus in the *Commorientes*, his translation of that play. These changes he would not himself, of course, have described as "spoiling"; that is the unpleasant word used by his critic. What he omits to mention is that he made other changes which were not borrowing but original invention. Through a misunderstanding of these passages, "contaminate" has come in textual criticism to mean "combine"; but it cannot be shown that the word ever had this sense in Latin.

Terence's second play was perhaps the *Hecyra* ("Mother-in-law"); but this play failed twice (as the two prologues explain) before it was finally produced in 160 B.C. The *Phormio*, one of his liveliest plays, was translated from Apollodorus' *Epidicomenos* ("Litigant"). His masterpiece, the *Adelphi*, was produced at the funeral games of Aemilius Paulus (father of the younger Scipio) in 160 B.C.

It is noteworthy that Terence uses the prologue no longer to explain the plot but (after the manner of the Aristophanic *parabasis*) to reply to his critics (*Andr.* 5–7). In using his Greek models, apart from "borrowing" from a second original, Terence permits himself various liberties. Names are altered, Greek allu-

sions toned down, characters slightly changed, individual scenes remodeled (e.g., *Eunuchus* 539 ff. is turned from a monologue into a dialogue of considerable power by Terence's addition of a character, Antipho). These and other changes are attested by Donatus; they show beyond doubt that Terence was not content to be a mere translator, but tried by delicate changes to improve on Menander himself.

The central interest in Terence's plays is character. In almost every play there is at least one pair in like circumstances who behave differently; *quam uterque similis suis!* (*Phor.* 501): "how like each is to himself!" The charm of Terence's Latin and his lack of comic power are referred to by Julius Caesar, whose judgment seems to have been generally endorsed in antiquity.

**Influence.**—The simplicity of Terence's Latin and his moralizing tone made him a favourite author in the middle ages. He was not, however, moral enough for Hrosvitha, the nun of Gandersheim, who in the 10th century wrote six Christian comedies modeled on Terence but portraying the victory of chastity over lust; there is a farcical element. One of the first Italian comedies, Ariosto's *I Suppositi* (1509), owes something to the *Eunuchus*, and was itself the model for George Gascoigne's *The Supposes*, the first prose comedy of English literature (1566). In the early 16th century Dutch schoolmasters developed what is known as the education-drama, or the "Christian Terence." Molière based his *L'École des maris* (1661) on the *Adelphi* and his *Les Fourberies de Scapin* (1671) on the *Phormio*. The *Phormio* was performed by the boys of St. Paul's school in 1528. George Chapman's *All Fools* (acted 1599) is based on the *Heautontimorumenos*, with borrowings from the *Adelphi*. Charles Sedley's *Bellamira* (1687) is adapted from the *Eunuchus*; Thomas Shadwell's *The Squire of Alsatia* (1688) from the *Adelphi*. The *Andria* is imitated in Steele's *The Conscious Lovers* (1722), the *Adelphi* in Fielding's *The Fathers, or The Good-Natured Man* (posthumously published 1778). Thornton Wilder's novel, *The Woman of Andros* (1930), is partly based on the *Andria*.

**BIBLIOGRAPHY.**—The *editio princeps* appeared in 1470. Other editions: R. Bentley (1726); A. Fleckeisen, "Teubner Series" (1898); R. Kauer and W. M. Lindsay, Oxford Classical Texts (1926); J. Marouzeau, 3 vol. with French trans., in the "Budé Series" (1942–49); S. Prete (1954); cf. G. E. Duckworth, *The Nature of Roman Comedy* (1952); W. Beare, *The Roman Stage*, 2nd ed. (1955); E. Paratore, *Storia del teatro latino* (1957). (WM. BE.)

**TERESA, SAINT,** OF ÁVILA (OF DE JESÚS; TERESA DE CEPEDA Y AHUMADA) (1515–1582), Spanish mystic, originator of the Carmelite Reform, and author of spiritual classics. Great as was her accomplishment in active life, to which the Discalced Carmelite houses still stand witness, it was the beauty of her interior life, as it is revealed in her writings, that causes her to be looked upon as one of the world's greatest religious women. Her spiritual works are read as widely today as they ever were: a list of Spanish books in print dated 1964 shows no fewer than nine editions of her *Obras completas* to be available.

Teresa de Cepeda was born in Ávila, in central Spain, on March 28, 1515, the daughter of a well-to-do *hidalgo*. In her *Life* she describes her father as "a man of prayer, charitable to the poor, and fond of reading good books," and her mother, "devoted to us children, remarkably beautiful, and gifted with common sense." Teresa's seven brothers became colonial officials in South America; her two sisters married and lived in Spain. When Teresa was 14 her mother died; two years later her father sent his vivacious daughter to a boarding school. Illness forced her to leave after a year and a half, and while convalescing she began to give serious thought to her vocation in life.

Despite her father's opposition, Teresa, at the age of 21, went to the Carmelite Convent of the Incarnation in Ávila and became a novice for the religious life. Within 2 years her health collapsed, and she was an invalid for 3 years. While recuperating at her uncle's country home, the young nun, through the reading of religious classics, developed a great love for mental prayer, which she later defined as "friendly conversation with Him Who we know loves us." After her recovery, however, the young sister at Incarnation became spiritually tepid; although observing the community exercises, she had, she later wrote, "ceased to pray."

For 15 years Teresa continued in a state that she describes thus: "On the one side God was calling me; on the other, I was following the spirit of the world. It was as if I wished to reconcile two contradictories. So distressful was the conflict that I do not know how I endured it." One day in 1555, while praying before a representation of the thorn-crowned Christ, her heart was touched, and she made her complete surrender to Christ; a new life of prayerful union began, but not without a heroic struggle with herself and hostility from many of her associates. Frequently during her life, this very intelligent, matter-of-fact, and humble woman calmly relates, Christ conversed with her and directed her activities. Among her spiritual directors were the celebrated Dominican theologian Domingo Báñez and two saints: the Jesuit Francis Borgia and the Franciscan Peter of Alcántara.

**Carmelite Reform.**—In 1558, after 22 years in the convent, Teresa began to consider, for those who would aspire to it, the restoration of Carmelite life to its original observance of austerity. It required complete separation from the world in order that the nuns could more intently meditate on the law of the Lord and, through a prayerful life of penance, exercise what Teresa termed "our vocation of reparation" for the sins of mankind. Such a life was enjoined by what is known as the Primitive Rule of Carmel, as approved by Innocent IV in 1247 for the Carmelite friars (the nuns did not come into existence until 1452). It reflects the tradition of prayer and penance that goes back, it is said, to the prophet Elias (Elijah) and his spiritual descendants of the Christian era, the hermits of Mt. Carmel. (See CARMELITES.) But in the 14th and 15th centuries the religious orders had relaxed their observance. By the standards of the Primitive Rule, Incarnation Convent was patently lax. Not, indeed, morally lax—Teresa herself assures us of this and extols the lives of many of her sisters. But separation from the world, dedicated contemplation, uniform evangelical poverty, and penitential observance lived more in pious esteem than in daily practice.

In 1562, after prolonged prayer and consultation, Teresa with the authorization of Pope Pius IV and the encouragement of the bishop of Ávila opened the first convent of the Carmelite Reform, with four women as its first subjects, in an old building she named in honour of St. Joseph. From municipal as well as religious personages came a storm of hostility that took on tornado proportions, especially because the convent would exist without endowment; but Teresa, undaunted, insisted on poverty and subsistence only through the alms of the people. Five years later the Carmelite general came from Rome and not only approved the Reform but directed Teresa to establish more convents. Before he left Spain, he gave her another mandate: to endeavour to establish monasteries of men who would observe the Primitive Rule. In 1567, while at Medina del Campo, where she had founded her second convent, Teresa met a young Carmelite priest, Juan de Yepes, later to be canonized as St. John (*q.v.*) of the Cross. In this brilliant friar, Teresa knew that she had the man to initiate the Carmelite Reform for men. A year later John with two other friars opened the first monastery of the Reform at Duruelo; before her death, Teresa saw 12 such monasteries founded.

Although she desired nothing more than to live in the prayerful quiet of the cloister—she describes her first five years at St. Joseph's as "the most peaceful years of my life"—Teresa, obedient to the will of her religious superiors, spent most of her last two decades of life in the arduous work of establishing and nurturing more convents of the Reform. After the Ávila foundation, Teresa, in spite of frail health and great difficulties, founded 16 more convents, from Seville in the south of Spain to Burgos in the north, "without so much as a penny to buy one."

In 1575, while Teresa was at the Seville convent, a controversy erupted in the Carmelite family that almost obliterated the Reform. It was primarily a jurisdictional dispute between the observants of the Mitigated Rule, called the Calced ("Shod"), and the friars of the restored Primitive Rule, known as the Discalced (*i.e.*, wearers of sandals). Teresa had foreseen the trouble and had endeavoured to prevent it, but her efforts were of no avail. As mother of the Reform, she naturally became the centre of the acrimonious quarrel. She was ordered by the Carmelite general,

to whom she had been grossly misrepresented, to go to a convent in Castile, remain in obscurity, and desist from founding more convents. Four years later, mostly because of the efforts of the Spanish king Philip II, who knew and admired Teresa, and the papal nuncio, a solution was effected whereby the Carmelites, nuns and friars, of the Primitive Rule were made independent in jurisdiction; this was confirmed by a rescript of Pope Gregory XIII in 1580.

At the age of 64, broken in health but with a spirit vibrant as ever, Teresa was directed to resume the work of the Reform. In journeys that covered hundreds of miles, she took up her exhausting mission of visitations, settling administrative problems, and establishing five more convents. The greatness of this very human as well as holy woman—among whose many gifts was a sparkling sense of humour—does not lie so much in her visible achievements as in her interior life of prayer, heroic obedience, and deep humility. En route to Ávila from Burgos, Teresa was stricken at her Alba de Tormes convent with a cerebral hemorrhage and repeated heart attacks. She died there on Oct. 4, 1582; 40 years after her death, she was canonized by Pope Gregory XV, and her feast is celebrated on Oct. 15.

**Writings.**—Through four centuries the writings of St. Teresa have been acknowledged spiritual classics. Her most celebrated work is the *Life*, written under obedience to her directors, which she never intended for the general public; it is not only the story of her life but, like the *Confessions* of St. Augustine, the history of a great soul. *The Book of the Foundations* describes the establishment of her convents and is interspersed with salutary exhortations. Her writings on the progress of the Christian soul toward God are recognized masterpieces: *The Way of Perfection*, *The Interior Castle*, *Spiritual Relations*, *Exclamations of the Soul to God*, and *Conceptions on the Love of God*. Thirty-one of her poems and 458 of her letters are extant.

In the history of Christian mysticism and spirituality, these writings occupy a special place because of their distinctive combination of great ardour and utter candour. Always reluctant to claim any spiritual prerogatives for herself on the basis of the mystical experiences granted to her, Teresa felt constrained, in spite of her diffidence, to acknowledge these experiences as the gift of God and to praise him for them. Interpreters of prayer and of the mystical life, such as Friedrich von Hügel and Friedrich Heiler, have therefore drawn upon her writings for much of their documentation, and believers in search of inspiration and spiritual strength have likewise found them here. As Heiler has said, "St. Teresa, with her masterly analysis from which every modern psychologist may learn, stands unsurpassed among all the mystics and one might call her the woman psychologist among the saints. Yet in her the simplicity and intensity of her experience are not injured by the psychological self-analysis. Her achievement has been to experience and at the same time to observe the experience" (*Prayer*, Oxford University Press, New York and London, 1932).

The first collected edition of St. Teresa's works was published at Salamanca in 1588; several revised editions were produced subsequently, including that by P. Silverio, *Obras de S. Teresa de Jesús* (1924). The manuscript of the *Life*, in the saint's handwriting, is in the Escorial, near Madrid; original manuscripts of her other writings are in various libraries and convents in Spain. The first English translation of the *Life* appeared in 1611; another in 1870 by David Lewis, reedited in 1910 by Benedict Zimmerman. The Benedictines of Stanbrook Abbey, England, have made notable translations of her works. An English version of her writings is by E. Allison Peers, *The Complete Works of St. Teresa* (1946), and, by the same translator, *The Letters of St. Teresa* (1949).

**TERESINA**, chief city and capital of the state of Piauí, Brazil, is located on the right bank of the Parnaíba River about 220 mi. (354 km.) from the port of Parnaíba and about 200 mi. (322 km.) from São Luís in Maranhão. Pop. (1960) 100,006.

The city was founded in 1852 as the new capital of Piauí, and since then it has become the chief commercial centre of the middle Parnaíba valley. It has textile factories, sugar refineries, distilleries, soap factories, and sawmills. It ships out cattle, hides, goat skins (from the *caatinga* or uplands of eastern Piauí), maize, rice, cotton, and manioc. It is reached from Parnaíba by shallow-draft river steamers; a railroad which terminates at Timon (Maranhão), on the left bank of the river opposite Teresina, connects with São Luís and carries much of the commerce of the middle Parnaíba valley. An all-weather highway connects with Fortaleza in Ceará; and there are air services to all parts of Brazil. Formerly called Theresina, the city was named after the empress Teresa Cristina Maria of Brazil. (P. E. J.)

**TERHUNE, ALBERT PAYSON** (1872–1942), U.S. novelist and short-story writer, famous for his popular stories about dogs, was born in Newark, N.J., on Dec. 21, 1872, the son of a Presbyterian clergyman, Edward Payson Terhune (1830–1907) and Mary Virginia Hawes Terhune (1830–1922), herself popular for romantic novels and books on household management written under the pen name of Marion Harland. He received his first schooling in Paris and Geneva, Switz., while his father was serving as chaplain of the American churches of Rome and Paris. Terhune graduated from Columbia University, New York City, in 1893, traveled in Egypt and Syria, and returned to New York, joining the staff of the *New York Evening World* in 1894. His first book was *Syria from the Saddle* (1896); his first novel, *Dr. Dale* (1900), was written in collaboration with his mother. He wrote assiduously in his spare time to free himself from journalism and published more than 12 books before he left the *Evening World* in 1916.

In 1919 appeared the first of his popular dog stories, *Lad, a Dog*. He had moved to a farm near Pompton Lakes, N.J., which he named "Sunnybank," and there for the rest of his life he wrote, bred prize collies, fished, and hunted. He wrote more than 25 books after 1919, nearly all of them novels in which dogs played conspicuous parts, including *Bruce* (1920), *The Heart of a Dog* (1924), *Lad of Sunnybank* (1928), and *A Book of Famous Dogs* (1937). He also wrote two autobiographical books, *Now That I'm Fifty* (1925) and *To the Best of My Memory* (1930). He died at Sunnybank on Feb. 18, 1942.

**TERM.** In traditional logic (*see* LOGIC: *Traditional Logic*) a term is properly the subject or predicate of a categorical proposition. Aristotle so used the Greek word *horos* (limit), apparently by an analogy between the terms of a proportion (*see* below) and those of a syllogism. *Terminus* is the Latin translation of this, used for example by Boëthius. Hence in medieval logic the word came to be used also for common and proper names generally (*see* NAME [IN LOGIC]); and even for what were called syncategorematic terms—words such as *and*, *if*, *not*, *some*, *only*, *except*, which are incapable of being used for the subject or predicate of a proposition (*see* MEANING). In everyday English, the meaning of term has been broadened still further, to that of an item of terminology, any word or phrase with a particular meaning.

In mathematics, the terms of a fraction (*see* FRACTION) are the numerator and denominator. The terms of a proportion are the four numbers which enter into the proportion (*see* ALGEBRA) or the corresponding numerical expressions that denote such numbers. Similarly the terms of a sum are the numbers which are added together to constitute the sum, or the numerical expressions denoting them. In this sense an infinite series (*see* SERIES) is thought of as a sum of an infinite number of terms; and a polynomial (q.v.) is a sum of a finite number of monomials which are the terms of the polynomial. (A. O. C.)

**TERMAN, LEWIS MADISON** (1877–1956), U.S. psychologist specialized in intelligence testing and in the research study of gifted children. He was born on a farm in Johnson County, Ind., on Jan. 15, 1877. He took his graduate training at Clark University, Worcester, Mass., and from 1910 until his retirement in 1943 was professor of psychology and education at Stanford

University. Terman published the first important and widely used individual intelligence test in the U.S., the Stanford-Binet, which he described in *The Measurement of Intelligence* (1916). In connection with this test, he employed the term IQ (intelligence quotient), signifying a score on an intelligence test that takes account of both chronological age and mental age in such a way that the average child of any age has an IQ of 100. Working with a group of other psychologists during World War I, he was largely responsible, also, for the first notable group intelligence tests, the Army Alpha and Army Beta (*see* further PSYCHOLOGICAL TESTS AND MEASUREMENTS).

Terman recognized the great importance to society of identifying intellectually gifted children and of providing them early in their lives with exceptional educational opportunities. In 1921 he selected 1,500 California children whose IQ's were over 140 (about 0.5% of the population) and began to study their development. He continued this research until his death 35 years later, by which time he had obtained definitive evidence that gifted children tended to be healthier and more stable emotionally than the average child and that they retained their high ability in adulthood. Terman's last progress report on this continuing study was *The Gifted Child Grows Up* (1947). He died at Palo Alto, Calif., on Dec. 21, 1956.

*See* also GIFTED CHILDREN.

*See* E. G. Boring, "Lewis Madison Terman," in *National Academy of Sciences, Biographical Memoirs* (1959). (R. R. S.)

**TERMEZ**, a town and capital of Surkhan-Dar'inskaya (Surkhan-Darya) Oblast' of the Uzbek Soviet Socialist Republic, U.S.S.R., lies on the right bank of the Amu Dar'ya (Amu-Darya) and on the Karshi-Dushanbe (Stalinabad) railway. Pop. (1959) 22,063. With a maximum temperature of 50° C (122° F), it is one of the hottest towns in the U.S.S.R. It has occupied two previous sites: the earlier, on the Amu Dar'ya, flourished as a trading centre from the 10th century, but was destroyed by the Mongols in 1220; the later was on the Surkhandar'ya. The older site is preserved as a state monument and contains a 9th-century mausoleum. Termez has a cotton ginning factory and other light industries. (G. E. Wr.)

**TERMINI IMERESE**, a town in the province of Palermo, northern Sicily, 20 mi. (32 km.) ESE of the town of Palermo. Pop. (1961) 23,171. At the centre of the Gulf of Termini Imereze, it lies on two levels connected by steps and the Serpents' Road. The Church of the Annunziata has a superb 16th-century cupola. The town's well-known thermal saline springs were praised by Pindar. The town is on the coastal road and railway from Palermo to Messina. There is intensive cultivation of citrus fruits, vines, and olives, and a flourishing hotel industry.

The ancient Thermae Himerenses was founded by the Carthaginians in 408 B.C. after the destruction of the nearby Himera. The tyrant Agathocles was born there in 361 B.C. (M. T. A. N.)

**TERMINUS** (Lat. "boundary stone"), originally, in Roman cult, a stone or post set up in the ground with the following religious ceremonies. A hole was dug and a fire lighted; a victim was sacrificed and its blood poured into the hole, together with incense, fruits, honey, wine, and the ashes of the sacrifice. Then the boundary stone, which had been previously anointed and crowned with garlands, was placed upon the hot ashes and fixed in the ground. Anyone who removed a boundary stone was accursed (*sacer*) and might be slain with impunity; a fine was afterward substituted for the death penalty. From this sacred object evolved the god Terminus. On Feb. 23 (the end of the old Roman year) the festival called Terminalia was held. The owners of adjacent lands assembled at the common boundary stone and each garlanded his own side of the stone. An altar was set up and offerings of cakes, grain, honey, and wine were made. Later a lamb or a suckling pig was sacrificed. The proceedings closed with songs to the god and general merrymaking in which all the members of the family and the servants took part.

A similar festival was held at the old boundary of the Roman territory between the fifth and sixth milestones on the road to Laurentum. When the Capitoline temple was to be built the auguries forbade the removal of one of these *termini* (a boundary

mark of some old precinct?) and it was enclosed within the walls of the new sanctuary, an indication of the immovability of such stones and of the permanence of the Roman territory.

**TERMITE**, the name for usually pale-coloured, soft-bodied insects of the order Isoptera (see INSECT). They all live in large social colonies. Termites cause severe economic damage to wooden structures and wood products, particularly in the tropics and warm temperate regions. An account of termite biology and social life is given in the article SOCIAL INSECTS.

**General Features.**—The wingless nymphs and workers are frequently whitish, a characteristic that has resulted in the misnomer "white ants." Worker termites have thick waists and can be readily distinguished from worker ants which have wasplike constrictions of the abdomen. Furthermore, flying termites have four membranous wings of almost equal size whereas flying ants have smaller hindwings. Termites, unlike ants, have a basal crack or suture in each wing by means of which the wings are shed in a fraction of a second following the colonizing flight.

Termites are found in greater numbers of species and individuals in the tropics than in the colder regions. From temperate North America, 45 species are recorded; from temperate Eurasia and North Africa, 40 species are known.

Grass, leaves and dead wood form the principal diet of termites, although some tropical species eat the organic humus of soils, a few eat fungi and some eat living woody plants.

**Control Measures.**—Methods to control termites are often necessary throughout the United States and occasionally in southern Ontario and British Columbia in Canada. Damage in Eurasia extends northward to a line through southern France, the Balkan countries, the southern U.S.S.R., southern and coastal China, Korea and Japan. Although termites are not spreading northward in their natural habitat, a few species have been introduced and established in heated buildings in many northern cities. Because most termites are soft-bodied and easily injured by arid conditions, they cannot live long after being exposed to dry air. The sterile workers and soldiers are blind and have a neutral reaction to light if the humidity is high enough. The majority of species in the fairly advanced family Rhinotermitidae and in the most advanced family Termitidae are dependent upon soil moisture for their existence. The species in one fairly primitive family, Kalotermitidae, are called dry-wood termites. These excavate their nests and chambers in dry or damp wood above ground.

**Dry-Wood Termites.**—Dry-wood termites are seldom found north of the Gulf states, New Mexico and Arizona, or east of the northwestern Pacific states. *Kalotermes flavicollis* causes damage in the Mediterranean countries, and some other species cause economic damage as far north as southern Japan. One largely tropical genus, *Cryptotermes*, can live in the dry wood of furniture. The dry-wood termites show no external indications of their presence but they may be detected by the characteristically hollow sound heard on tapping the wood near their galleries. When their chambers are exposed, accumulated masses of dry pellets of excrement may pour out.

Infestation may be prevented by inspection of lumber prior to its use, by placing screens (20 meshes per inch) over openings

in the building, by using wood that has been treated chemically in commercial plants, by dipping wood in a solution of pentachlorophenol (5%, in a light petroleum oil) for three minutes and by covering exterior woodwork with heavy coats of paint around holes and cracks.

Liquid insecticides (trichlorobenzene; 2% chlordane in oil; 5% pentachlorophenol in oil; 6% DDT in oil; and benzene hexachloride) sprayed into the inhabited termite galleries often give satisfactory results. Poison dusts (smelter dust, white arsenic, paris green and 50% DDT) blown upon the termites in the galleries may effectively kill the entire colony within a few weeks.

**Subterranean Termites.**—Most control measures against the subterranean termites are designed to prevent their gaining entry into wooden structures which are in close contact with the soil. It is much easier to build relatively resistant structures than it is to eradicate termites after infestation. Precautions include cement foundations, a distance of at least 18 in. between the ground and any untreated wood, and ventilation under houses without basements. Cement grout, coal-tar plastic cement or coal-tar pitch should be used to seal off all holes around pipes in foundations below the ground level. Copper or zinc metal shields may be placed between woodwork and the top of cement foundations. All joints in the metal should be tightly sealed and the outer edges should be at least three or four inches wide beyond the sill and bent downward at an angle.

Subterranean termites that have already gained access to a building will die if their contact with soil moisture is broken. Soil poisons around the foundations are effective for several years. The poison is placed in a deep trench or in holes bored with a soil auger 18 in. apart. Heptachlor, aldrin, dieldrin, lindane and chlordane are the poisons usually used.

**TERMS, DISTRIBUTION OF.** In logic a term is said to be distributed in a proposition when explicit reference is made to its whole extent or extension. Otherwise (that is, not only when reference is made explicitly to a part only of the extension of the term, but when explicit reference is simply not made to its whole extension) it is said to be undistributed. Thus, in a proposition of the form *No S is P* both the subject and the predicate are distributed. In the form *Some S is P*, neither *S* nor *P* is distributed. In *All S is P*, *S* is distributed, but *P* is not. Lastly, in *Some S is not P*, *S* is not distributed, but *P* is. Briefly, only universal propositions distribute the subject term (*S*), and only negative propositions distribute their predicate (*P*). Naturally, singular terms (including proper names used as singular terms) are always distributed, for they only refer to one object, and cannot refer to less.

The importance of the distribution of terms arises from the fact that it is a principle of formal inference that no term may be distributed in the conclusion unless it was distributed in the premisses. That is why, e.g., *All S is P* can only be converted into *Some P is S* (not into *All P is S*), and *Some S is not P* cannot be converted at all.

**TERN**, a gull-like aquatic or marine bird, often called a sea swallow because of its trim shape and buoyant flight. Terns constitute the subfamily Sterninae of the family Laridae. They are nearly worldwide in distribution, many of them ranging far during migration, the most notable long-distance migrant being the Arctic tern (*Sterna paradisaea*) (see MIGRATION, BIRD). In length, terns range from about 8 to 22 in., and, as compared with gulls, they are more slender, longer-winged, and shorter-legged. Many species are mainly gray and white; others range from almost black to pure white.

They may be grouped broadly as follows. Noddy terns (*Anous* species), dark-coloured, and the white fairy tern (*Gygis alba*) are mainly tropical and subtropical. Inca tern (*Larosterna inca*), dark-coloured, with white plumes on side of head, are found in

JOHN H. GERARD

TERMITES EATING YELLOW PINE.  
GREATLY MAGNIFIED

Peru and northern Chile. Capped and crested terns, many mainly pearl gray above, paler (to white) below, with a black cap or small-fish black crest, are arctic circumpolar species. Marsh terns, largely dark-coloured; little terns (length 8-10 in.), which have partial black cap; and the large-billed tern (*Phaetusa simplex*) are South American.

Terns are colonial breeders, with no nest to a well-formed one, on the ground. The fairy tern lays one egg, on a horizontal tree limb. Most terns lay two eggs. One brood a year is the rule but the sooty tern (*Sterna fuscata*), also known as wideawake, breeds at about nine-month intervals. The majority obtain their food by diving from the air. They eat a variety of aquatic life, such as invertebrates and small fishes, and terrestrial insects that are blown into the water. They seldom eat larval lobsters or any significant amount of commercially important fish. In some parts of the world, the eggs, especially of the sooty and noddy terns, are gathered in great quantity for human food. (R. S. Pr.)

**TERNATE**, a volcanic island of Indonesia in the *kabupaten* (regency) of Maluku Utara (North Moluccas). It is the northernmost of the line of islands off the western coast of Halmahera, Indon., which stretch southward to the Batjan Archipelago, and lies 18 mi. (29 km.) west of the Halmahera coast. It is 6 mi. wide and has an area of 41 sq.mi. (105 sq.km.). Pop. (1957 est.) 33,964. The island consists mainly of a conical volcano 5,627 ft. (1,715 m.) in height, with three peaks (Arfat, Madina, and Kekan), its curious formation being due to many extremely destructive eruptions. In the last four centuries there has been constant volcanic activity on Ternate, the worst being the eruption in 1763. An eruption in 1840 destroyed nearly every house in the town of Ternate. The northern half of the island suffered most from volcanic activity. On the southern and eastern coasts are forests and luxuriant vegetation, with a good deal of cultivated land on the flat strip by the shore; vegetation extends even far up the mountainside. Rice and maize (corn) are grown, also sage, coffee, pepper, nutmegs, and fruit.

The local inhabitants are of very mixed blood, probably Malay predominating, but with Papuan elements. They have a language of their own, written in the Arabic character, and are Muslim by religion; there are some Christians also.

**TERNATE TOWN**, with an estimated (1957) population of 23,500, lies on the southeast coast of the island, at the foot of the mountain. It is a picturesque settlement, the houses interspersed among a wealth of trees, with the volcano for a background. The port on the bay between Ternate and Tidore (to the south) is a regular place of call for interisland vessels. Ternate was once a leading centre of clove cultivation. Although it is the headquarters of the regency of Maluku Utara, it has only the shadow of its former importance. Its small trade is made up chiefly of copra and nutmeg.

In the 12th century, Javanese controlled the clove trade, later to be joined by Malaccan and Indian merchants. In the century before the advent of the Europeans, Ternate became the seat of a Muslim sultanate. The first Western visitor was the Portuguese Francesco Serra (1512). Soon thereafter Portuguese ships from Malacca began to visit Ternate to load cloves. Fearing Spanish competition upon the arrival in 1521 of the ship "Victoria" (of the Magellan expedition), the Portuguese obtained a treaty from the sultan whereby they secured (on paper at least) the monopoly of the spice trade and the right to establish a fort on Ternate (1522).

Commercial and religious conflicts caused the expulsion of the Portuguese in 1574. In 1579 Sir Francis Drake called at the island, but the visit was never followed up by English trading vessels. In 1599 Jacob van Neck established Dutch relations with Ternate. After an attack by a Spanish fleet in 1606 the sultan placed himself under Dutch protection and gave them the spice monopoly in his territories. To maintain the monopoly and maintain high prices, the Dutch East India Company restricted production by cutting down clove trees. The serious decline in welfare led to a popular revolt in 1650. It was sternly suppressed and ended in a new agreement with the sultan; cultivation of cloves was henceforth forbidden in Ternate and other islands of

the northern Moluccas. Another revolt in 1683, this time led by the then ruling sultan, was also put down and the sultan reinstated as a mere vassal of the company. Executive power was gradually gathered in Dutch hands until the Japanese occupation during World War II and the subsequent independence of Indonesia in 1949. (E. E. L.; J. O. M. B.)

**TERNEPLATE**: see TINPLATE AND TERNEPLATE.

**TERNI**, chief town of Terni province in Umbria, central Italy, and the seat of a bishop, lies 62 mi. (100 km.) NNE of Rome by road on the Nera River. Pop. (1961) 94,194. Its important remains are a Neolithic village, cemeteries of the Villanovan period, an amphitheatre, and Roman walls. The cathedral, originally built in 550, was reconstructed in the mid-17th century. The Romanesque Church of S. Salvatore was erected over a Roman building, possibly a temple of the Sun; the 9th-century Church of S. Alò belonged to the Knights of Malta. Churches of the 13th century are S. Lorenzo, S. Pietro, S. Cristoforo, and S. Francesco (1265) with a fine bell tower added in 1345. In the Paradisi Chapel is a fresco of the Last Judgment (Giotto School). Non-religious architecture includes the Torre Barbarasa (13th century); the Palazzo Mazzancolli (14th century); and the Renaissance Palazzo Spada, the last work of Antonio Picconi da Sangallo who died at Terni in 1546.

The chief attraction near Terni is the Cascata delle Marmore (4 mi. [6 km.]). These falls were created by the consul Manius Curius Dentatus by deflecting the waters of the Velino River into the Nera River below; they are now used for hydroelectric power.

Terni is a railway junction on the Rome-Ancona line and an industrial centre. Manufactures include iron and steel, arms, machinery, textiles, sugar, soap, and *pasta* products. There are electrochemical plants, distilling, and tanning. Vegetable and fruit growing on irrigated land is intensive.

Terni is on the site of the ancient Interamna Nahars, which was occupied by Sulla. In the 14th century it became a dominion of the church. The town was heavily damaged during World War II.

**TERNI PROVINCE** is watered by the Tiber and the Nera and is hilly and well irrigated. Area 819 sq.mi. (2,122 sq.km.); pop. (1961) 222,720. Important towns are Narni (birthplace of the emperor Nerva), with light industries; Nera Montoro, with a chemical industry; Piediluco, which has a picturesque lake; and Orvieto, famed for its Romanesque-Gothic cathedral. Acquasparta and San Gemini are thermal spas. Wine is exported and ceramics and wrought iron are produced. (M. T. A. N.)

**TERNIFINE FOSSILS**, so-called after the local name for part of the Eghriss plain south of Mascara (q.v.), Alg.; excavations for a new village, in 1870, revealed there (on the west side of a Muslim cemetery, used as a sand pit, and consisting of silt that filled a Pleistocene lake that existed about 450,000 years ago) a wealth of fossil mammal bones and Abbevillian-Acheulian stone tools. The cemetery barred excavation except in the sand pit, which became flooded after 1888 when diggers tapped an artesian spring. Between 1954 and 1956 the French paleontologist Camille Arambourg and co-workers pumped out the water to find considerable remains of extinct African fauna and a great quantity of primitive artifacts of European mid-Pleistocene type.

Three human jawbones and a fragment of skull from the pit (closely resembling *Pithecanthropus* and *Sinanthropus*; qq.v.) were identified as belonging to a being whom they named *Atlanthropus mauritanicus*. The discovery shed light on the nature of the Abbevillian-Acheulian toolmakers, concerning whom speculation continued despite the abundance of their products throughout the Old World.

**BIBLIOGRAPHY**.—M. Boule and H. V. Vallois, *Fossil Men* (1957); C. B. M. McBurney, *The Stone Age of Northern Africa* (1960); C. Arambourg and R. Hoffstetter, *Le Gisement de Ternifine* (1963). (CA. A.)

**TERNOPOL'**, a town and administrative centre of Ternopol' Oblast' in the Ukrainian Soviet Socialist Republic, U.S.S.R., stands on the left bank of the upper Seret, 75 mi. (121 km.) ESE of

L'vov (Lvov). Pop. (1959) 52,245. Originally belonging to the princes of Galicia (*q.v.*), Ternopol' later passed to Poland and, in the first partition of Poland in 1772, to Austria. After World War I Ternopol' was returned to Poland, but was annexed by the U.S.S.R. in 1939. During World War II the town suffered almost total destruction. Its present importance is as a regional centre and railway junction. Five lines (from L'vov, Droboych, Chernovtsy, Khmel'nitskiy [Khmel'nitski], and Korosten') converge on Ternopol', linking it to all parts of western Ukraine. It has relatively small-scale light industries, chiefly processing food-stuffs. Natural and artificial leather working and the manufacture of footwear are important. Reinforced concrete items are also produced.

TERNOPOL' OBLAST' was formed in 1939 from territory annexed from Poland. Area 5,367 sq.mi. (13,900 sq.km.); pop. (1959) 1,085,586. The *oblast* lies athwart the Volyno-Podol'skaya Upland, with its southern boundary along the Dniester River, to which the greater part drains. The rolling, loess-covered hills of the upland are cut up by river valleys, notably that of the Seret. Intensive agriculture, even on slopes, has led to the widespread development of erosion gullies. The whole *oblast* is in the forest-steppe zone, but only small patches of oakwood survive. Soils are fertile chernozems, slightly podzolized in the west.

Of the 1959 population only 17% were urban, living in 14 towns and 12 urban settlements. The towns are all small local centres engaged in sugar refining and the processing of other farm products. A little lignite is mined. The economy is overwhelmingly agricultural, and the density of the rural population is one of the highest in European Russia. Grains, mainly rye, wheat, and maize (corn), occupy over half the arable land. Sugar beet leads the industrial crops, especially in the east. Sunflowers are grown in the west and some tobacco in the south, while hops are generally important. The widespread potato crops are used for human and animal consumption and for distilling. (R. A. F.)

**TERPANDER** (fl. c. 675 B.C.), of Antissa in Lesbos, Greek poet and musician, is said to have won a prize in Sparta at the feast of Apollo Karneios in the 26th Olympiad (676/2). He is alleged to have founded the first "establishment" (Gr. *katastasis*) of music at Sparta before the Second Messenian War, and to have "invented" the seven-stringed *kithara* (which was already known in Minoan times). He was proverbially famous as a singer to the *kithara* (see *LYRE*), and is credited with important developments in the songs (Gr. *nomoi*) for that instrument, but the authenticity of the few surviving literary fragments ascribed to him is at best doubtful. It is probable that when Sappho spoke of the primacy of the Lesbian singer she was thinking of the fame won by Terpander.

For fragments and allusions, see J. M. Edmonds, *Lyra Graeca*, vol. 1, 2nd ed. (1928) in the "Loeb Series"; see also *Poetae melici Graeci*, ed. by D. L. Page, pp. 362-363 (1962). (JN. A. D.)

**TERPENES** are members of a class of naturally occurring hydrocarbons (*q.v.*) of the general formula  $(C_5H_8)_n$ , the name being derived from turpentine, which is a mixture of terpenes. Terpenes occur in the essential oils of many plants and in the gummy exudates (oleoresins) of many trees and shrubs. The term terpenes is frequently used in a broader sense to include compounds which contain oxygen and may be regarded as being derived from the terpene hydrocarbons.

The terpenes and their derivatives are broadly classified according to the number of  $C_5H_8$  units which they contain, and range in molecular size from volatile oils of molecular formula  $C_{10}H_{16}$  to giant molecules such as that of natural rubber containing about 4,000  $C_5H_8$  units. The classes are: monoterpenes,  $C_{10}H_{16}$ ; sesquiterpenes,  $C_{15}H_{24}$ ; diterpenes,  $C_{20}H_{32}$ ; triterpenes,  $C_{30}H_{48}$ ; tetraterpenes,  $C_{40}H_{64}$ ; polyterpenes,  $(C_5H_8)_n$ . Nearly all of the terpenes possess carbon skeletons that may be regarded as being

built up from isoprene units. The isoprene units may be linked in a variety of ways leading to acyclic, monocyclic and polycyclic sub-classes within the broad classes of terpenes, depending upon the number of carbon atom rings that result. Myrcene (I), an acyclic monoterpene; limonene (II), a monocyclic monoterpene;  $\alpha$ -pinene (III), a bicyclic monoterpene; and vitamin A (IV), an oxygen-

ated, monocyclic diterpene, exemplify this further classification and the dotted lines indicate the division of the carbon skeletons into isoprene units.

The problems in molecular structure presented by the terpenes have challenged the imagination and skill of organic chemists since the latter part of the 19th century. The first investigations were mainly concerned with the structures of the monoterpenes ( $C_{10}H_{16}$ ) but as those structural patterns became familiar and techniques for investigation were developed, attention was turned increasingly toward the terpenes containing 15 to 40 carbon atoms.

Typically the establishment of the structure of a terpene follows the sequence: isolation; purification; degradation by oxidation to simpler compounds of known structure; postulation of a structure based on the results of the degradation; and validation of the structure by unambiguous synthesis.

## MONOTERPENES

The monoterpenes are isolated from their natural sources by distillation of the plant matter with steam. They are volatile oils, less dense than water, and have normal boiling points in the range  $150^{\circ}$ – $185^{\circ}$  C. Purification is usually achieved by fractional distillation at reduced pressures or by regeneration from a crystalline derivative. Acyclic monoterpene hydrocarbons are few in number and it is their oxygenated derivatives which are more widespread in nature and of greater importance. Important oxygenated

acyclic monoterpene derivatives include the terpene alcohol citronellol (V) and the corresponding aldehyde citronellal (VI), both of which occur in oil of citronella, as well as citral (VII), found in lemon-grass oil, and geraniol (VIII), which occurs in Turkish geranium oil.

Citronellal is converted by treatment with acid into the monocyclic monoterpene alcohol isopulegol from which a mixture of stereoisomeric menthols (IX) is produced on catalytic hydrogenation. The process is used commercially to supplement the natural sources of menthol (oil of peppermint), widely used as a flavouring and in medicinal preparations. Citral (VII), upon reduction with sodium amalgam, yields geraniol (VIII), an important com-

built up from isoprene units  $(C-C=C-C-C)$  in various combina-

tions and the early recognition of this common structural feature (O. Wallach, Isoprene Rule, 1887) was of great help in the elucidation

ponent of rose perfumes. Citral may be condensed with acetone to

yield the important intermediate  $\psi$ -ionone (X) from which  $\beta$ -ionone (XI) results on cyclization with acid. Although  $\beta$ -ionone cannot be regarded as a terpene, it is of great importance as a starting material for the synthesis of vitamin A (IV) and as a component of violet-scented perfumes.

Limonene (II), an oil of normal boiling point  $177^\circ \text{C}$ ., is a major component of orange and lemon oils and is typical of the monocyclic monoterpene hydrocarbons. Others of this class are terpinolene,  $\alpha$ - and  $\beta$ -phellandrene and  $\alpha$ -,  $\beta$ - and  $\gamma$ -terpinene, all of which have the same carbon skeleton as limonene and differ only in the location of the two carbon-to-carbon double bonds. Limonene is optically active as are most of the terpenes and their derivatives which contain an asymmetric carbon atom, started in the formula of limonene (II) (see STEREOCHEMISTRY). The racemic form of limonene is known as dipentene, and results from the dimerization of isoprene,  $\text{CH}_2=\text{C}(\text{CH}_3)\text{CH}=\text{CH}_2$ . Limonene is converted to isoprene by contact with a heated metallic filament. Few commercial uses, other than as flavourings, exist for the monocyclic monoterpene hydrocarbons. Menthol (IX), which has already been mentioned, and the oxygenated derivatives

$\alpha$ -terpineol (XII) and 1,8-terpin (terpin hydrate) (XIII) are chemicals of commerce. Mixtures of 1,8-terpin,  $\alpha$ -terpineol, terpinolene and the terpenes result from the treatment of  $\alpha$ -pinene (III) with acid, and the mixture finds use as "pine oil," an inexpensive disinfectant, deodorant and wetting agent.

Of normal boiling point  $156^\circ$ ,  $\alpha$ -pinene (III) is representative of the bicyclic monoterpenes, and the most abundant and important monoterpene. It is the major component of ordinary turpentine which is prepared from pine trees or stumps either by extraction followed by rectification or by distillation with steam. It is a major component of "sulfate turpentine," a by-product of the manufacture of paper, and is important as a component of paints and varnishes and as a raw material for the production of a wide

variety of products employed in chemical industry.

Its use in coating materials depends upon its good properties as a solvent and upon its conversion by air oxidation into a polymeric, resinous film. Its function as a starting material for conversion to more useful products results from its abundance and its structure, which has a high degree of chemical reactivity. The chemical reactions of  $\alpha$ -pinene have been studied more thoroughly than those of any other terpene and the study has contributed

greatly to the understanding of molecular rearrangements (*q.v.*) in organic chemistry.

Treatment of  $\alpha$ -pinene with acids under various conditions leads to a host of products among which are terpinolene, the terpenes,  $\alpha$ -terpineol (XII) and terpin (XIII) previously mentioned, and in addition borneol (XIV), fenchyl alcohol (XV) and the hydrocarbon camphene (XVI).

The formation of the latter three compounds involves molecular rearrangement and advantage has been taken of the structural changes to provide a commercial synthesis of the important bicyclic terpene ketone, camphor (*q.v.*).

### SESQUITERPENES

Sesquiterpenes,  $\text{C}_{15}\text{H}_{24}$ , are isolated from their natural sources by distillation with steam or by extraction since they are of lower volatility than the monoterpenes. They are purified by fractional distillation *in vacuo* or by chromatography. The sesquiterpenes demonstrate an even greater complexity of structure than the monoterpenes, and oxygenated sesquiterpenes are commonly en-

countered. Two arrangements of isoprene units are found in bicyclic sesquiterpenes, the cadalene (XVII) and the eudalene (XVIII) types, and the carbon skeleton of a sesquiterpene may frequently be determined by heating it with sulfur or selenium to effect dehydrogenation to the corresponding naphthalenic hydrocarbons: cadalene, 4-isopropyl-1,6-dimethylnaphthalene; or eudalene, 7-isopropyl-1-methylnaphthalene. In those cases where sulfur dehydrogenation fails to yield information about the carbon skeleton of a sesquiterpene a systematic degradation by oxidation to compounds of known structure is necessary.

Cadinene (XIX), the principal component of oil of cubeb, is a typical sesquiterpene of the cadalene type. It is an optically active oil of normal boiling point  $275^\circ \text{C}$ . Selinene (XX), present in celery oil, is typical of the eudalene type.

### DITERPENES

Phytol (XXI), an oxygenated acyclic diterpene, is an important building block of the chlorophyll molecule from which it is obtained on saponification. The arrangement

of isoprene units in phytol is identical with that in vitamin A (IV), a monocyclic diterpene derivative, and is typical of the head-to-tail arrangement of isoprene units found in most terpenes.

The commercial importance of the bicyclic monoterpene  $\alpha$ -pinene is paralleled in the diterpenes by abietic acid (XXII), a tricyclic carboxylic acid which constitutes the major portion of rosin. Rosin is the nonvolatile portion of the oleoresin of members of the pine family and is the residue left after the isolation of

turpentine. Rosin is used as such in the production of varnish and coating materials and, in the form of its sodium salt, for sizing

XXII

paper, as an emulsifying agent in producing synthetic rubber and in yellow laundry soap. It is among the cheapest organic acids.

### TRITERPENES

The acyclic triterpene hydrocarbon squalene (XXIII) constitutes more than half of the liver oil of certain species of sharks and is otherwise rather widely distributed in nature. It has been found in other fish-liver oils, in vegetable oils, in fungi and in human earwax and sebaceous secretions. The biochemical importance of squalene as a metabolic intermediate in the biosynthesis of cholesterol (XXIV) was demonstrated by the use of radioactive carbon labeling. The formula of squalene (XXIII) is arranged so as to show its relationship to the structure of cholesterol (XXIV).

Although cholesterol is not a terpene, the demonstration that it has a terpene as precursor in metabolism represented a major

XXIII

XXIV

advance in understanding the biochemical relationship between the two important classes of compounds involved.

Although tri- and tetracyclic triterpenes are known, by far the most abundant triterpenes found in nature are those having five

XXV

carbon rings. The pentacyclic triterpenes, either free or combined with sugars in glycosides (saponins), occur in all parts of

many plants. Although the structures of many of the pentacyclic triterpenes are not known in full detail, that of  $\beta$ -amyrin (XXV) is well established and exemplifies the important structural features of this class of substances. The best source of  $\beta$ -amyrin is elemi resin although it has been isolated from more than 50 plant sources. The carbon skeleton of  $\beta$ -amyrin bears a striking relationship to those of squalene (XXIII) and cholesterol (XXIV) and it has been suggested that squalene is a common precursor of the pentacyclic triterpenes and the sterols in biosynthesis.

### TETRATERPENES

The large class of yellow, orange or red, fat-soluble plant and animal pigments known as carotenoids are classed as tetraterpenes although they have in general the molecular formula  $C_{40}H_{56}$  rather than  $C_{40}H_{64}$  as required by  $(C_5H_8)_8$ . The fact that their structures can be built up from isoprene units justifies their classification as terpenes. The carotenoids are isolated from their natural sources by solvent extraction and purified by chromatography. Lycopene (XXVI), the red pigment of the ripe tomato, exempli-

XXVI

fies the class of acyclic tetraterpenes. The dotted lines in the formula show the division into isoprene units, and it is to be noted that the usual head-to-tail attachment of isoprene units is interrupted in the centre of the molecule with a single tail-to-tail

XXVII

attachment that produces a symmetrical structure. This feature is generally encountered in the tetraterpenes, as is the long series of alternating single and double, carbon-to-carbon bonds (conjugated system) which is responsible for the absorption of light and hence the bright colours of the compounds.

The most important and abundant tetraterpene is  $\beta$ -carotene (XXVII), the principal yellow pigment of the carrot;  $\beta$ -carotene is of nutritional importance since the animal organism is apparently able to cleave the molecule at the point of symmetry with the production of vitamin A (IV). The role of vitamin A and structurally related terpenoid molecules in the synthesis of the pigments in the eye necessary for vision has been demonstrated.

### POLYTERPENES

Rubber, which occurs in the latex of the rubber tree, is a polyterpene hydrocarbon,  $(C_5H_8)_n$  where  $n$  is 4,000-5,000. Chemi-

XXVIII

cal degradation by oxidation and X-ray diffraction studies have revealed a repeating unit (XXVIII) in rubber. Division into isoprene units is indicated. The vulcanization of rubber involves the establishment of cross linking between the chains through sulfur atoms. Gutta-percha differs from rubber in the way in which the methyl ( $CH_3$ ) groups are arranged; in gutta-percha they are on opposite sides (trans arrangement) of the chain and in rubber they are on the same side (cis arrangement).

(R. H. EN)

**TERRACINA**, a town and port of Latina Province in central Italy, between the Ausonian Mountains and the Tyrrhenian Sea, is 64 mi. (103 km.) SE of Rome. Pop. (1961) 28,590.

The town was occupied by the Volscians, who called it Anxur, and about 400 B.C. it passed under Roman domination, under whom it was known as Tarracina, becoming an important city on the Appian Way from Rome to Capua and Brundisium. Between the end of the republic and the first two centuries of the empire, the city assumed great importance, as witnessed by the remains of the forum; the sumptuous temples, baths, and theatres; and the remains of the villas of the emperors Tiberius, Galba, and Vitellius.

The new town lies close to the sea, with the old town on the slopes above. There are municipal parks, a town hall (1958), and a museum. Though the town was damaged during World War II, many ancient structures remain. Dominating the town are the ruins of the Temple of Jupiter Anxur and the ancient Anxur wall. The cathedral of S. Cesareo (1074) stands over the ancient temple of Roma and Augustus, the remains of which can be seen in the outer walls.

Fishing, food preserving, floor surfacings, and electrical appliances are the major industries, and muscatel grapes are exported.

**TERRA COTTA**, generally considered, may apply to all kinds of fired clay, but has come to refer chiefly to a fairly coarse, porous type which when fired assumes a colour ranging from dull ochre to red and is most frequently left unglazed.

Baked clay, because it can be easily manipulated before it is fired and is relatively durable, has been used throughout the world since earliest times for pottery and sculpture and for many architectural purposes. While clays vary widely in composition in different areas, all are subject to fusion by heat into a hard substance varying in colour, porosity and strength in accordance with its content and the temperature to which it has been subjected. (See CLAY AND CLAY MINERALS.)

The most characteristic feature of objects in terra cotta is their obvious dependence on the plasticity of the material before it is hardened by fire. The clay when wet can be pressed or poured into molds; it may be cut, incised and folded; and it is responsive to the slightest pressure of the hand. Because of this, early artists sometimes attempted bolder designs in terra cotta than in more resistant materials. The coarser clays, however, do not readily lend themselves to sharp edges and precise definition of forms. Early works in terra cotta illustrate both the advantages and limitations of these material qualifications. For this reason there is often a superficial similarity between simply made terra-cotta works so far divided by time and distance as early Greece and the more modern cultures of Latin America.

Not only do the varied characteristics of the material, especially in primitive cultures, influence the form terra-cotta works are likely to take, but technical considerations in the procedure of firing also play a part. It is necessary that an object modeled in clay be thoroughly dry before being subjected to the intense heat of the kiln. In drying, and again in firing, the clay shrinks, and if one part dries much more rapidly than the rest it may crack and break away. It is necessary, therefore, to maintain a nearly equal thickness and avoid solid masses of clay of which the outer layers, drying more quickly, would shrink and crack. While this presents little difficulty in the making of pottery and low reliefs, it forces the sculptor to adopt complex methods for work in the round.

It was early found that very small figures could be fired successfully when solid, but larger works had to be rendered hollow before firing. There are three general methods by which this can be done: by pressing thin layers of clay into a mold (or pouring the clay in liquid form, called slip, into the mold and pouring off the residue after a thin shell has set); by hollowing out the heavier portions of the work; or by building up the work from the beginning with hollow forms. Throughout the history of terra cotta the first method has been the most popular. Not only does it permit evenness of drying and therefore successful firing, but it affords the possibility of multiplying the image indefinitely once the mold is made. The exploitation of this technique can be seen in the architectural decoration of the Etruscans, the figurines from Tanagra

with their variously assembled parts, the repeated figures in Chinese tomb sculpture and the elaborate ornamentation of the Certosa at Pavia. But for a figure to be produced in an uncomplicated mold, deep undercutting must be avoided. As a result the surfaces are likely to be relatively unbroken, depending for contrast on incised pattern or applied colour.

Of importance particularly for the other methods of achieving a hollow form is the fact that an object to be fired can have no interior framework of a foreign substance. Since clay in a moist state will support little weight unassisted, constant attention must be paid to the relative size of the supporting members. The effect of this consideration may be seen in much modern terra-cotta sculpture built up from hollow forms. While it may place some limitations on the artist, it often imparts to the work a formal unity of a character peculiar to this use of the medium.

Colour has been used extensively in terra cotta ranging from the mat colours of applied slip (fine clay suspended in water) to the brilliant glazes of which the earliest examples come from Egypt and the near east. Since often the colour was not fired and thus fused with the surface, many once colourful objects have lost much of their original effect and appear in misleading simplicity to the modern eye. Few past cultures seem to have prized, as do modern sculptors, the native texture and colour of terra cotta.

Much of the use of terra cotta has been of a purely utilitarian kind since it is a relatively cheap, durable product of versatile nature. In places such as Mesopotamia and parts of Italy where stone has not always been easily accessible, it has served in architecture both for structure and ornament. In the 19th century, with the growth of iron construction, terra cotta commercially produced in the form of tile and sculptured ornament again became popular. It was light, adaptable to the many styles of ornament in demand and, as was discovered late in the century, could form a fireproof case for the vulnerable iron structure. See AEGEAN CIVILIZATION; CHINESE SCULPTURE; POTTERY AND PORCELAIN; TILE. (J. C. T.)

#### GREEK, ETRUSCAN AND ROMAN

Good clay was abundant throughout Greece and Italy and was used in ancient times for pottery, sculpture and in architecture. (See also GREEK ART; ROMAN ART; ETRUSCANS.)

**Literary Sources.**—Pliny in his *Natural History* gives an account of the art of terra-cotta sculpture (*plastica*), which contains much useful information. The most significant statements are the following: (1) Boutades of Sikyon invented the art of making portraits in terra cotta and antefixes in the form of human beings (xxxv, 151); (2) Rhoikos and Theodoros of Samos invented the technique of clay modeling long before the Bacchiades were exiled from Corinth; i.e., before about 657 B.C. (xxxv, 152); (3) Eucheir, Diopos and Eugrammos of Corinth introduced the art of clay modeling into Italy in the 7th century B.C. (xxxv, 152); (4) Damophilos and Gorgasos decorated the temple of Ceres in Rome, which was dedicated in 493 B.C. (xxxv, 154); (5) Vulca was called from Veii to Rome at the time of Tarquinius Priscus (616–578 B.C.) to make the cult statue of the temple of Jupiter Capitolinus, which was dedicated after the flight of Tarquinius Superbus in 510 B.C. (xxxv, 157). Pliny (xxxv, 158) and Plutarch (*Publicola*, xiii, 1–2) both speak of Etruscan terra-cotta sculpture with wonder and admiration; Vitruvius (iii, 3, 5) refers to terra-cotta pedimental sculptures as an "Etruscan fashion."

Some of these statements square with the facts as archaeology has revealed them, others do not. The tradition that the art of clay modeling was practised in Greece in early times is borne out by discoveries of small terra-cotta figures dating back to the early Bronze Age and of larger ones from the 7th century B.C. That this art was introduced into Italy by Greek artists and flourished there especially in the late Archaic period—when the temples of Ceres and Jupiter Capitolinus were dedicated—is substantiated by discoveries of a large number of terra-cotta statues and reliefs of that epoch in Etruria showing strong Greek influence. Moreover, that some of these Etruscan and Greek sculptors worked also in Rome is suggested by the fragments of important terra-cotta sculptures of that period that have been found there. On the other

hand Pliny (perhaps quoting Varro) evidently confused some of his dates. Excavations at Samos have shown that Rhoikos and Theodoros were active in the 6th not the 7th century B.C., and if Vulca worked on the cult statue of the temple of Jupiter Capitolinus, which was dedicated after 510 B.C., Tarquinius Superbus rather than Tarquinius Priscus must have given the commission.

The terra-cotta sculptures of Greece, Etruria and Rome consist of statues, statuettes and reliefs.

**Statues.**—Terra-cotta statues were particularly popular in Italy, where marble was scarce until the opening of the Carrara quarries in the 1st century B.C., and in Cyprus. Discoveries at Kalydon, Thermos, Olympia and the Agora of Athens, however, show that terra-cotta sculptures must have been commoner in Greece than was once thought. Practically all served as decorations of temples.

That Pliny's and Plutarch's admiration of Etruscan terra-cotta statues was justified is borne out by the discoveries of such statues, large and small, throughout Etruria and etruscanized Latium. The life-sized statues of Apollo, Herakles and Hermes from Veii rank, both artistically and technically, among the greatest achievements of this kind. They once adorned the ridge pole of a temple, as shown by the terra-cotta bases found with them. Many other examples, both single figures and groups (some partly in relief), served as acroteria and antefixes of temples or came from pediments. Excellent specimens, chiefly of the Archaic period, a few of the later 5th and the 4th century B.C. and many of the Hellenistic epoch have been found at Caere (Cerveteri), Satricum (Conca), Falerii (Civita Castellana), Lanuvium (Lanuvio), Veii (Veio), etc.

Another common use for statues in terra cotta among the Etruscans was for figures placed on the lids of sarcophagi. Life-size archaic examples from Caere are in the Louvre and in the Villa Giulia museum, later ones in the British museum, the Archaeological museum in Florence and elsewhere. A large number of terra-cotta urns for holding the ashes of the dead, in the form of miniature sarcophagi, also have reclining figures on the lid. They date from the 3rd and 2nd centuries B.C. and often portray the deceased with great realism.

The style of these Etruscan sculptures, like that of Etruscan paintings, at times shows strong Greek influence, but it mostly has a marked local flavour. The spirit is sometimes gayer, at other times more morose or fiercer than in the Greek counterparts.

With the extended use of marble for sculpture in Italy in the 1st century B.C. terra-cotta statues became scarce. Relatively few have come to light in Pompeii and elsewhere in the Roman domains.

**Technique.**—Etruscan and Greek terra-cotta statues were not molded but modeled, from the bottom up, with coils and wads of clay, in thick walls. The clay was mixed with sand and grog to provide porosity, diminish the shrinkage and avoid distortion; and over this a coating of finer clay was generally added. Before firing the surface was painted, the prevalent colours being white, brownish red and black. The firing of such large statues as the Apollo of Veii and the warriors in New York required great care. The kiln must have been built round them, as they could hardly have been moved in the green state. The temperature has been computed to have been about 960° C., approximately the same as that used in firing Greek pottery. In the sanctuaries of Asclepius at Epidaurus and Corinth, as well as in Italy, there have been found life-size votive figures consisting generally of heads or of parts of the body that had been diseased and subsequently cured. They date mostly from the 4th to the 1st century B.C. and are made in molds in well-leigated clay.

**Statuettes.**—The commonest use of terra cotta was for small figures not over six or seven inches in height. They have been found in tombs and sanctuaries, on many different sites in Greece, Cyprus, Rhodes, Asia Minor, north Africa, Italy and Sicily, and range from the Bronze Age to the Roman period. Among the earliest are primitive figures from Cyprus, with planklike bodies or birdlike features. The painted and glazed statuettes of the Minoan period from Crete are more sophisticated in their modern-looking costumes, with full skirts, bare breasts and narrow waists. The Mycenaean and geometric figures, though schematic, are often in

lively, lifelike poses. Women, horsemen, children and animals are favourite subjects. Particularly interesting are groups from Cyprus and elsewhere, consisting of men in chariots, dancers, warriors, in the so-called snow-man technique, modeled with great freedom.

From the 7th and 6th centuries B.C., all over the Mediterranean, the Greek terra-cotta statuettes reflect the changing styles in sculpture. Those of the 7th century show close contact with the orient both in subjects and renderings. In the 6th century the standing and seated female figure is favoured, the latter being generally shown holding a flower or other offering in one hand or with a child on her lap. Quantities of such statuettes have been found in votive deposits near the temples of Paestum (Poseidonia), the Heraion of Foce del Sele and other sites. The nude male standing figure, the so-called *kouros* type, is comparatively rare; only isolated examples have been found; e.g., at Perachora and Veii. Among the most attractive statuettes of the late Archaic period are figures of women engaged in household tasks, horsemen, barbers and animals, found mostly in Boeotia. Though summarily modeled, they have vivacity and style.

Fifth-century terra-cotta statuettes continued the types prevalent in the preceding times, especially of seated and standing women, but with more freedom in the rendering of features and drapery. They are not as common as in the preceding or succeeding periods, but some are worthy products of their epoch and show the repose and serenity of the contemporary marble sculptures. A common type of the first half of the 5th century is a female mask or bust, generally hollow at the back, which is found both in central Greece and Rhodes.

From the late 4th century B.C. the types are more numerous. They represent no longer always divinities or votaries, but mostly the people of their time. Women are particularly popular. They are shown in graceful poses—standing, leaning against a pillar, walking or sitting, doing their hair, carrying a child or playing games. Comparatively few young men or children or animals appear, but an old nurse with a child in her arms, or a teacher with his pupil and particularly actors in their characteristic outfit are not uncommon. Since many of such statuettes were first found at Tanagra, in Boeotia, during the 1880s, they are still commonly called Tanagra figurines, though similar examples later came to light in other parts of Greece.

In the Hellenistic period the centres of manufacture in terra-cotta statuettes, as well as in marble and bronze sculpture, shifted from Greece proper to Asia Minor. In the little town of Myrina extensive discoveries were made in 1880–82 and other sites later yielded rich harvests. The new spirit of Hellenistic art is reflected in these statuettes. Instead of the quiet, gentle women, youths and children prevalent during the preceding periods, there are people in lively attitudes with draperies rendered in multiple folds going in different directions. Mythological subjects, especially flying Victory and Eros, as well as caricatures occur. Many Hellenistic terra-cotta statuettes from Italy and Sicily formed part of the grandiose vases then prevalent; e.g., the Canosa and Centuripe wares. Those from Egypt are naturally influenced by the beliefs there current, representations of Horus, Bes and an oriental Aphrodite being popular.

The same Hellenistic types continue throughout the Roman age, as extensive discoveries at Pompeii and throughout the Roman empire, including Gaul, Belgium and Britain, indicate. The Roman terra cottas from Egypt again stand apart, being of brown, local terra cotta and representing Egyptian deities in a Greco-Egyptian style. Of special interest are the large statuettes that reproduce famous sculptural works, e.g., Polyclitus' "Diadumenus," found in Asia Minor and elsewhere.

**Technique.**—The technique of terra-cotta statuettes is of course different from that of statues. They are made of well-leigated clay and molded; comparatively few are modeled by hand. A mold was first made and baked to considerable hardness; moist clay was then pressed into it, of the thickness required, and allowed to dry; the resultant shrinkage made it easily removable from the mold. The back was made in another piece, sometimes summarily by hand, with a venthole for evaporation. Often heads and arms were

made separately, in different molds and variously combined, but in spite of a limited number of molds there is great diversity. In the words of E. Pottier, "there are many sisters, but few twins." An engobe or slip of white clay was added (while the ware was still leather hard) and when bone dry the figures were fired to a moderate heat. Finally colours were added in tempera—blue, red, pink, yellow, brown, violet and rarely green for the garments, brownish for the skin of men and boys, pink for the cheeks of women, auburn for hair, red for lips and brown or blue for eyes. Gilt sometimes occurs for details, such as jewelry, or as an all-over covering; also sometimes black. Few figures now retain their original colours; in most only the drab terra cotta remains.

After the extensive discoveries at Tanagra had come to a stop toward the end of the 19th century, the popular demand for the charming figurines naturally persisted and as a result many forgeries were made which found ready acceptance with the public. Among them are mythological groups and single figures in affected attitudes that can easily be distinguished from the Greek originals. Sometimes, however, the figures were made from molds taken from ancient statuettes, and then only the somewhat blurred surface, or the addition of inappropriate details or mistakes in the application of the colours betray the hand of the forger.

**Reliefs.**—In addition to terra-cotta statues and statuettes, reliefs played a large part in Greek, Etruscan and Roman art. They served as decorations of temples and other buildings, especially in those countries where a wood and clay construction instead of stone was in use. Many examples of all periods have come to light in Italy and Asia Minor, mostly of the Archaic and Hellenistic periods, some of the 5th and 4th centuries B.C. They are decorated with floral designs, preferably palmettes, scrolls, rosettes, meanders and spirals, combined in effective patterns, or they have figured representations, such as chariot races or banquets or mythological subjects. Revetments of this kind have been found at Larisa (Larissa) in Asia Minor, Sardis in Lydia, southern Italy and throughout Etruscanized central Italy. Many simas and antefixes have decorative features in relief consisting of lions' masks, female heads and other motives.

Besides architectural reliefs, votive ones are common. Two classes call for special mention—the Tarentine and the Locrian. At Tarentum many examples have been found which range from Archaic to Hellenistic times and apparently served as votive offerings to local deities. They represent local divinities and heroes and are made in local clay in a broad, smooth style. Dionysus and his cycle were especially popular. The Locrian reliefs are generally small and meticulously executed. Again local cults dictated the subjects. The majority were offerings to Persephone and related to the cult of the dead. They, too, were a local product, made in local clay. The period of production was relatively short; almost all extant examples belong to the first half of the 5th century B.C.

The Melian reliefs, so called because many have been found in the island of Melos, were apparently not votive but served for the decorations of chests. They are often of fine quality and may be assigned to the second quarter and the middle of the 5th century. Mythological subjects predominate, but scenes from daily life also occur. There were of course many other uses for terra-cotta reliefs. They served as decorations of small altars and of all sorts of vessels, and even of furniture. The Etruscan urns of the 3rd and 2nd centuries above mentioned generally have reliefs on their sides depicting scenes from Greek mythology, such as the combat of Theseus and the Centaur, or the death of Polyneices, in Hellenistic Greek style. Applied reliefs appear on vases from Centuripe and other Hellenistic wares. Necklaces and other jewelry were sometimes made in terra cotta and gilded, chiefly for sepulchral use.

The Romans used terra-cotta reliefs on both the interior and exterior of buildings. Cicero speaks of fixing such reliefs (*typoi*) in the corner of his little atrium. Circular holes served for fastening them by means of plugs to the walls. The subjects are mostly mythological. Dionysus and his satyrs and maenads are especially popular. Occasionally Roman subjects occur. Lamps were generally made of terra cotta in antiquity and the Roman ones are usually decorated with reliefs on their upper surface.

**Technique.**—The majority of these reliefs—Greek, Etruscan and Roman—were made in molds, and there are many repeats. Sometimes a mold was taken from an existing relief and was then naturally smaller in size because of the two successive shrinkages. Like the statues and statuettes these reliefs were all gaily coloured, but much of the polychromy has disappeared.

**Use in Buildings.**—Lastly, terra cotta served purely utilitarian purposes, especially on the roofs of buildings. Roof tiles—both flat ones and curved, covering ones—were often made of terra cotta; also the covering slabs along the raking cornice of the pediment, the cornice itself, the gutters and parts of the pediment. Many such plain terra-cotta slabs have been found in ancient sanctuaries that had terra-cotta roofs and revetments. Sometimes terra-cotta slabs were decorated with paintings. From a temple of the 7th century B.C. at Thermon in Acarnania slabs that served as metopes have been preserved, some with their painted decoration still visible. At Klazomenai terra-cotta sarcophagi of the Archaic Greek period with painted scenes have come to light, and terra-cotta slabs with painted decoration have been found lining walls of Etruscan tombs. Bricks in wall construction were much used; they were not always fired, but merely sun-dried.

**Collections.**—The most representative collections of Greek terra cottas are in the British museum, the Louvre and the museums of Berlin, Naples, Paestum, Syracuse, Athens, Olympia, Boston and New York. The Etruscan ones may best be studied in the museums of Florence, Perugia, the Villa Giulia museum in Rome, the British museum, the Ny-Carlsberg Glyptotek in Copenhagen and the Metropolitan museum in New York. Most of the Roman examples are in Rome, Naples, Pompeii and in the provincial museums of France, England and Germany. (G. M. A. R.)

## MODERN EUROPE

Neither for architectural decoration nor for free sculpture was terra cotta a frequently used medium between the end of the Roman empire and the 14th century, although the simple technical procedures were kept alive in the making of pottery. By the 15th century, however, a notable revival was in full progress particularly in Italy but also in Germany. Terra cotta was then used in architecture in two distinctive ways. For brick architecture terra cotta, similar in colour and substance to the building material, formed the ideal decorative element and, molded or carved, served in its natural colour for elaborate friezes, window and door moldings and inset medallions. The church of St. Catherine, Brandenburg, is a highly decorated example of the German usage. In Italy fine examples are to be found throughout the north; indicative of the variety are the upper windows of the Municipal palace at Piacenza (begun 1281), the buildings of Biagio Rossetti (147–1516) in Ferrara and the Ospedale Maggiore (after 1456) in Milan. For contrast terra cotta was sometimes combined effectively with stucco or stone as in the apse of Santa Maria delle Grazie in Milan.

The second new use of terra cotta was in that of the highly glazed and coloured sculpture introduced in Florence early in the 15th century by the Della Robbias (*q.v.*). This work could be used more effectively in combination with marble and stone than could unglazed ornament, and it added a freshness of accent quite unparalleled. The effect was imitated both in France and Spain and the use of terra cotta, glazed and unglazed, spread throughout Europe. As a novelty Francis I had the entire façade of the little château of Madrid, which once stood in the Bois de Boulogne, richly decorated with enameled terra cotta by Girolamo della Robbia. But by the end of the 16th century terra cotta had once more fallen from popularity for architectural decoration, not to become a significant material again until the 19th century.

Free sculpture in terra cotta, too, found its revival in 15th-century Italy. Jacopo della Quercia, Donatello, Verrocchio and almost every other prominent sculptor left works in the material. Of particular interest, aside from the work of the Della Robbias, are the lifelike, coloured figure groups in Modena by Guido Mazzoni (1450–1518), who worked also in France, and the more sophisticated compositions of Antonio Begarelli (1498?–1565) in the same city. Sometimes terra-cotta sculpture was painted in natural colours, sometimes in imitation of marble or bronze, but

despite this and the skilful complexity of modeling, the characteristics of form identifiable with terra cotta are usually evident.

Aside from the completed works in terra cotta, not many in number, remaining from the 17th century, there exist many figures intended, as were those of Bernini, as studies or models for work in marble. Many of the 17th- and 18th-century portrait busts in terra cotta also were used for this purpose, but they are made striking by a faithfulness in the rendering of personal characteristics less frequently found in other media and exhibit a quality of immediacy not transferable to the sterner material. Among the most descriptive are the busts created in France during the 18th century by such sculptors as Jean Baptiste Lemoyne, Jean Jacques Caffieri and Jean Antoine Houdon.

It was also during the 18th century in France that small, freely modeled allegorical and mythological groups in fine terra cotta, less delicate than the contemporary porcelains but more robust in form and action, were produced in large numbers at Sèvres and met with great popular favour. Foremost among the creators of these fantasies was Claude Michel, called Clodion (1738-1814). Portrait statuettes of historical figures and famous contemporaries were also produced in profusion toward the end of the century but seem to have had a less universal appeal. The factories at Sèvres, closed during the French Revolution, were reopened under Napoleon but produced little more terra cotta.

**19th and 20th Centuries.**—While terra cotta was used by sculptors in the 19th century, especially by those working usually in bronze, it had little character of its own. When used commercially to reproduce figures for the popular market it was regularly disguised. Not until the early years of the 20th century, when the artist, taking a fresh interest in the properties of his medium, began to choose materials in which he could work directly, did it again assume positive character in art. Its use was linked to the revived interest in pottery, and many artists experimented with mixtures and glazes to produce effects of colour and texture. In architecture it was first revived by architects such as Karl Friedrich Schinkel (1781-1841), who became interested in earlier design in brick, and it served various historical styles and structural purposes throughout the century. The Architecture academy (1832-35) in Berlin by Schinkel and the Natural History museum (1873-80) at South Kensington, London, by Alfred Waterhouse are two very different examples. But the concern of modern architects and sculptors for the structural and aesthetic properties of their material has gained for terra cotta, along with other mediums, a new place in architectural ornament free from past usages and styles.

**TERRARIUM**, a transparent container, of glass or plastic panels or sides, with an adjustable lid, in which plants are grown usually in a naturalistic arrangement. It is actually a miniature

greenhouse providing conditions of soil moisture, humidity, warmth, and light required for the successful growth and cultivation of small plants.

Terrariums, also called Wardian cases, bottle gardens, glass gardens, and crystal gardens, are available in a wide variety of shapes and sizes; any suitable container can be used: an aquarium tank, candy jar, fish bowl, bottle, or homemade enclosure. When both plants and small animals are maintained together in such containers, the resulting microcosm is usually called a vivarium. Fernery, desertarium, and other terms are descriptive of the main type of plant life of a terrarium.

**History and Uses.**—The idea of raising plants in portable glass containers first occurred to early collectors who constructed crude glass-paneled boxes to carry exotic plants over long distances. Credit for perfecting the terrarium is usually given to Nathaniel B. Ward, an English botanist. His Wardian case, a popular feature in fashionable Victorian houses, was the precursor of the modern terrarium.

Terrariums can be both decorative and instructive. In modern heated apartments and houses, terrariums afford a degree of humidity, which can be fairly consistently maintained, required by many small tropical foliage plants, woodland plants, and orchids. Artistically designed terrariums are often displayed at flower shows, in classrooms, and in offices. Florists have spurred interest in glass gardening and often offer for sale established terrariums. A carefully planned and properly maintained terrarium or vivarium is an attractive way of illustrating the natural history of certain organisms and affords a controlled means of scientific observation and plant propagation.

**Preparation and Care.**—Woodland and jungle plants are easiest to maintain in the terrarium because of the constant humidity in the receptacle. Cacti and the other succulents can also be easily maintained if given slightly different conditions.

The most popular container is the rectangular aquarium, since the large opening permits the free use of both hands in arranging and planting a miniature woodland or desert. Next in favour is the drum-shaped aquarium, which, owing to the much smaller opening, requires some measure of patience and dexterous manipulation to create a picturesque effect.

Proper drainage is of utmost importance in the growing of plants in the terrarium, particularly for desert plants. This can be established by the use of porous soil and a bed of gravel or sand at the bottom of the container to the thickness of at least an inch. The incorporation of powdered or granulated charcoal in the soil is beneficial in preventing sourness or acidification. Since soil does not show attractively through the glass, it is recommended to line the walls with sphagnum or other woodland moss, face down, to the depth of the intended soil level, so that a green mat is presented to the outside.

The best soil for glass gardens is a mixture of sand, well-rotted leaf mold, and regular garden loam. The soil should be packed against the mossy lining and the objects placed in position, more soil being applied as the work progresses. Generally, soil in the terrarium should not exceed three inches in depth; of course this will depend materially on the size and shape of the container.

Plants should not be crowded together, as they will soon spread out and quickly spoil the naturalistic effect desired; it is better to use plants that grow slowly. If a desert garden is decided upon, suitable dwarf cacti should be chosen. Such a garden will give pleasure for many years if properly cared for. Other succulents adaptable to a desertarium are the small, rosette-forming *Haworthias*, seedling *Gasterias*, *Aloes*, *Stapelias* (which look very "cactusy" despite their thornless appearance), and *Euphorbias*. The sprawly *Kalanchoes* and *Bryophyllums* are less desirable and tend to become "leggy" and push their way up to the opening; they are not recommended unless they can be kept small by frequent pruning or pinching back the tips. Most temperate zone woodland plants, including tiny ferns, lichens, mosses, partridgeberry, native violets, holly, dwarf English ivy, and seedling evergreens do best in a cool room or sun porch (not in direct sunlight). For a warm room it is better to choose tropical plants such as African violet, small-leaved begonias, crotons, peperomia, selagi-

nella (a mosslike creeper), dwarf palms, bromelias, and seedling aroids like philodendrons and Chinese evergreens (*Aglaonema*).

When all the plants have been pressed into the soil, fine gravel or broken bits of rock should be sprinkled over the soil surface in desertariums and fir bark or wood chips in woodland terrariums. Such soil covers guard against any rot diseases that might creep in unexpectedly and at the same time prevent the soil from splattering over the plants and against glass sides when water is applied. Rocks, accessories, or novelty objects are often used to complete a picturesque scene, but care should be taken to avoid cluttering up the terrarium with meaningless and space-consuming bric-a-brac.

Particles of soil or gravel adhering to the plants should be removed with a small brush. In the woodland or jungle garden, water can be applied immediately after the terrarium has been planted to settle the soil and keep the roots moist; however, in the desert garden, water should be withheld for a few days so that any delicate root systems that have been injured or bruised in transplanting would be sufficiently healed. Thereafter, water need only be given in sparing quantities. During the summer months occasional "sweating" (allowing moisture to condense on the glass) will prove highly beneficial to desert plants, and for other plants the sweating process can be encouraged regularly throughout the year. Often the sweat bath will suffice as the only means of supplying moisture to the plants. The sweating process requires the placing of a piece of glass or lid over the opening of the terrarium and leaving it closed for several hours until condensation takes place.

Light and fresh air are two important factors in the successful management of terrariums. The woodland case will require less direct light and therefore can be placed in more sheltered places within the home, but a desertarium demands as much light as possible.

Ventilation can be regulated by adjusting the cover over the opening. Except when the sweating process is desired, the lid should be placed to allow about an inch or two of space for air to pass freely. If the terrarium always shows too much condensation and there is possibility of rot or fungus damage, the cover should be removed to permit the soil to dry out considerably. Terrariums require very little care when once established and should last for a number of years. Occasionally a plant may be lost and require replacement.

Glass gardening is one of the most fascinating hobbies that can be indulged by both adults and children. It is a worthwhile project for shut-ins, for children interested in nature subjects, and for the homemaker who wishes to ornament the home with a bit of the outdoors.

See M. Gilbert, *Starting a Terrarium* (1961).

(L. CV.)

**TERRE HAUTE**, a city of western Indiana, U.S., on the Wabash river, 73 mi. W.S.W. of Indianapolis, is the seat of Vigo county and one of the oldest cities in the state. The site was once a point of rendezvous for Indian tribes; nearby Fort Harrison was the scene of a battle between forces of Capt. Zachary Taylor and Tecumseh in 1812.

Terre Haute is on a plateau 50 ft. above the river, and the French name, meaning "high ground," was adopted by members of a small land company who platted the town in 1816. It became a key point on the National road (1835), the Wabash and Erie canal (1849) and the Richmond railroad (1852). When it was incorporated as a town in 1832 Terre Haute had a population of less than 1,000; by 1853, when it was chartered as a city, the population was almost 7,000.

The discovery of bituminous coal and other minerals paved the way for industrial development; by 1875 Terre Haute was one of the chief manufacturing centres in the midwest, producing steel and other commodities from resources available in the immediate area. Through World War I expansion of the city continued at a phenomenal rate.

After 1920 the rate of growth slowed, but Terre Haute's industrial output of chemicals, pharmaceuticals, plastics, clay and foundry materials, glass, clothing, foodstuffs and other products places it as one of the principal manufacturing cities of the state.

Pop. (1960) 72,500; standard metropolitan statistical area (SMSA; Vigo county) 108,458. In 1963 Clay, Sullivan and Vermillion counties were added to the SMSA, increasing its area from 415 to 1,499 sq.mi. and the population (1960 figures) to 172,069. (For comparative population figures see table in INDIANA: *Population*.)

Located in or near Terre Haute are: St. Mary-of-the-Woods, a Roman Catholic college for women organized in 1840; Indiana State Teachers college, established in 1870 as a normal school; and Rose Polytechnic institute, for men, founded in 1874 and named for Chauncey Rose, a local entrepreneur.

The city is the birthplace of Eugene V. Debs, labour and Socialist leader; the author Theodore Dreiser and his brother, the composer Paul Dresser (who changed the spelling of the family surname), were born nearby. Four miles from the city is a federal penitentiary.

(V. M. B.)

**TERRISS, WILLIAM** (WILLIAM CHARLES JAMES LEWIN) (1847–1897), a leading English actor of later Victorian days, was born in London on Feb. 20, 1847. After trying the merchant navy, sheep farming in the Falkland Islands and horse breeding in Kentucky, he went on the stage. He was immediately successful and appeared at the principal London theatres from 1868 until his death.

Terriss joined Henry Irving at the Lyceum theatre in 1880, playing such parts as Cassio, Mercutio and Henry VIII. He then became the leading man at the Adelphi theatre, where, as the hero of melodramas he became the idol of the public, his fine voice and appearance and breezy manner making a great appeal. His last appearance was made at the Adelphi in *Secret Service* under tragic circumstances. He was stabbed to death by a madman, Richard Prince, while entering the theatre on Dec. 16, 1897.

Terriss married Isabel Lewis, and their daughter Ellaline Terriss became a great popular favourite in both straight and musical plays, appearing with her husband, Sir Seymour Hicks. She was leading lady at the Gaiety, the Vaudeville, the Globe (then the Hicks), the Aldwych and many other London theatres, and also toured much of the world with great success.

See A. J. Smythe, *The Life of William Terriss* (1898).

(W. J. M.-P.)

**TERRITORIAL SYSTEM (U.S.)** From its inception as a nation, the United States has had land areas designated as territories, including western continental lands in the early years and overseas dependencies and trusteeships in more recent times. The federal Constitution in 1787 delegated to Congress the responsibility of establishing territorial governments and since that time four general types have developed: (1) organized or incorporated territories; (2) unorganized or unincorporated territories; (3) dependencies; and (4) trusteeships.

**Organized Territories.**—The pattern for organized territories was first established by the Ordinance of 1787, better known as the Northwest Ordinance. This act, perhaps the most important law enacted under the Articles of Confederation, instituted a plan of government for the region north of the Ohio River from Pennsylvania to the Mississippi River. This important ordinance, the model for the creation of other territorial governments, guaranteed basic civil and political rights in the territories. It also provided a three-stage plan by which all the territories could advance from the status of unorganized territory to organized territory to eventual statehood. By 1912 all contiguous territories had qualified for statehood.

The problem of territorial government became more involved with the purchase of Alaska in 1867, the annexation of Hawaii and the gaining of the Philippines, Guam, and Puerto Rico as an aftermath of the Spanish-American War in 1898, the purchase of the Virgin Islands in 1917, and the annexation of other small islands. The idea that all territories should eventually become states was discarded in favour of the view that some dependencies should retain a subordinate position.

The Supreme Court of the United States in the 1901 Insular Cases made a distinction between incorporated and unincorporated territories and held that Congress was restricted in its legislation regarding incorporated territories by constitutional limitations

while unincorporated territories were only partially protected by the constitution. With the admission of Alaska and Hawaii as the 49th and 50th U.S. states in 1959, the last of the existing organized territories disappeared.

**Unorganized Territories.**—The unorganized or unincorporated territories, under the jurisdiction of the Department of the Interior, had varying degrees of local self-government ranging from some autonomy to commonwealth status. By the 1960s all unincorporated territories had considerable voice in local matters. American Samoa was the only unincorporated territory whose residents were not granted U.S. citizenship. Its residents were still classed as nationals. Samoa had a locally elected legislature with a governor and a secretary appointed by the Department of the Interior.

The residents of Guam and the Virgin Islands were U.S. citizens and had control of legislative and judicial affairs, but their governors were appointed by the president of the United States. The policy of promoting self-government for these territories was furthered by filling territorial civil offices with native-born residents whenever practicable.

Both the Philippine Islands and Puerto Rico emerged from an unincorporated status to that of commonwealth status, and the Philippines gained complete independence in 1946. From the beginning of civil government in the Philippines the question of eventual independence had been raised and the way was prepared in 1935 with the creation of the Philippine Commonwealth. As a commonwealth, the Philippines had control of its domestic affairs but not of its foreign relations.

The residents of Puerto Rico were granted United States citizenship in 1917. By an act of Congress in 1952 the island became a self-governing commonwealth "closely associated with the United States," which remained responsible for the island's foreign affairs.

**Dependencies.**—Following World War II, the Pacific island dependencies, Midway, Wake, and several smaller ones, remained under the jurisdiction of the Navy Department and were not self-governing. The Panama Canal Zone was under the control of the Department of the Army, which appointed the governor who administered the civil government and headed the Panama Canal Company.

**Trust Territories.**—The Pacific island groups, the Carolines, the Marshalls, and the Marianas, all of which had been Japanese mandates under the League of Nations, were placed under the jurisdiction of the United States as Trust Territories by the United Nations in 1947.

The Marianas, with the exception of Rota, were administered by the Navy Department. The Carolines and the Marshalls and the island of Rota became the responsibility of the Department of the Interior. They were governed by a high commissioner who was responsible for their economic and social development and for their training in self-government. (H. B. ME.)

**TERRY, DAME ELLEN ALICIA** (1847–1928), English actress, famous for her great partnership with Henry Irving, was born at Coventry on Feb. 27, 1847. Her parents were well-known provincial actors and her sisters Kate, Marion, and Florence and her brother Fred all joined the theatrical profession. Her own first appearance on the stage was made on April 28, 1856, under Charles Kean's management, as the boy Mamilius in *The Winter's Tale*, at the Princess's Theatre, London. Two years later she played Prince Arthur in *King John* and won high praise. In 1864 she left the stage to marry the painter G. F. Watts, then 30 years her senior. Though the marriage was a failure, Watts refused her a divorce and later she eloped with Edward Godwin, the architect, who was the father of her children Edith and Edward Gordon Craig (q.v.).

Returning to the stage for a brief period in 1867, she played with Henry Irving for the first time as Katherine to his Petruchio in David Garrick's version of *The Taming of the Shrew* at the Queen's Theatre. Leaving the stage again, she lived in retirement at Harpenden, Hertfordshire, until 1874 when, at the instigation of Charles Reade, she returned to the stage in the part of Philippa in *The Wandering Heir* under his management at the new Queen's

Theatre. In 1875 she played Portia in the Bancrofts' production of *The Merchant of Venice* at the Prince of Wales's Theatre. Her performance won immediate acclaim and remained matchless throughout her career. In 1876 she married the actor Charles Kelly (E. A. Wardell).

In 1878 Miss Terry was engaged by John Hare at the Court Theatre, where her performance as Olivia, the title role in W. G. Wills's adaptation of Oliver Goldsmith's *Vicar of Wakefield*, attracted the attention of Henry Irving. When he assumed management of the Lyceum Theatre in 1878 he engaged her as his

BROWN BROTHERS  
ELLEN TERRY AS OPHELIA, ABOUT  
1879

leading lady. Her personal charm, vitality, and aesthetic judgment helped to make their histrionic partnership, lasting 13 years, the greatest the English stage has seen. Her first part at the Lyceum was Ophelia, and her performance, with its tender and authentic study of the derangement of an innocent mind, astonished those who recognized her genius in comedy. Her other Shakespearean impersonations at the Lyceum were Portia (1879), Desdemona (1881), Juliet and Beatrice (1882), Viola (1884), Lady Macbeth (1888), Katherine in *Henry VIII* and Cordelia (1892), Imogen (1896), and Volumnia in *Coriolanus* (1901). Other notable performances were those of the queen in Wills's

*Charles I* (1879), Camma in Alfred Tennyson's *The Cup* (1881), Margaret in *Faust* (1885), Nance Oldfield (1893), Rosamund in Tennyson's *Becket* (1893), Madame Sans-Gêne (1897), and Clarisse in *Robespierre* (1899).

With the Lyceum Company Ellen Terry toured the United States and Canada. In 1902 she appeared with Mrs. Kendall in Beerbohm Tree's revival of *The Merry Wives of Windsor* at His Majesty's Theatre. She and Irving played together for the last time at the Lyceum in a performance of *The Merchant of Venice* on July 19, 1902. In 1903 she presented several productions by her son Edward Gordon Craig at the Imperial Theatre, notably *The Vikings at Helgeland* by Henrik Ibsen. In 1905 she played "with indescribable fascination" Lady Cecily Waynflete in Bernard Shaw's *Captain Brassbound's Conversion*, but the hopes Shaw had held out to her in their famous correspondence of wider opportunities outside the Lyceum Theatre were not fulfilled, for she appeared afterward only in *Alice Sit-by-the-Fire* and in *Pinkie and the Fairies*. After her stage jubilee had been celebrated at the Theatre Royal in June 1906, she toured the English provinces and the United States giving witty and discerning lectures on Shakespeare's heroines. In 1907 she married the American actor James Carew.

In 1925 Ellen Terry received the grand cross of the order of the British empire. Her 80th birthday in 1928 was the occasion for tributes and messages from her countless admirers, headed by King George V and Queen Mary. She died on July 21 of that year at her house in Small Hythe near Tenterden, Kent, which now, as the Ellen Terry Memorial Museum, is the property of the National Trust. At her death the *Times* (London) wrote: "She was a woman of genius; but her genius was not that of the brain so much as of the spirit and of the heart. She was a poem in herself—a being of an exquisite and mobile beauty."

Her *Memoirs*, edited by Edith Craig and C. St. John, was published in 1933.

**BIBLIOGRAPHY.**—E. Gordon Craig, *Ellen Terry and Her Secret Self* (1931); Ellen Terry and Bernard Shaw: a Correspondence, ed. by C. St. John (1931); L. H. F. Irving, *Henry Irving: the Actor and His World* (1951).

**TERTIARIES**, associations of lay men and women in connection with the Roman Catholic mendicant (q.v.) orders. The

institution of tertiaries arose out of the Franciscan movement. When the immediate disciples of St. Francis had become an order bound by the religious vows, it became necessary to provide for the great body of laity who could not leave the world but who desired to carry out in their lives the spirit and teaching of the Franciscan movement. St. Francis therefore drew up a rule for those of his followers who were debarred from being members of the order of Friars Minor. At first they were called Brothers and Sisters of the Order of Penance; later, when the friars were called the First Order and the nuns the Second Order, the Order of Penance became the Third Order of St. Francis—whence the name tertiaries. (See FRANCISCANS: *Third Order*.)

In time a tendency set in for members of the Third Order to live together in community, and in this way congregations were formed who took the usual religious vows and lived a fully organized religious life based on the rule of the Third Order with supplementary regulations. These congregations are the regular tertiaries as distinguished from the secular tertiaries, who live in the world, according to the original idea. There are many congregations of regular tertiaries, both men and women. In 1883 Leo XIII caused the rule to be recast and made more suitable for modern times. In 1957 Pius XII issued a general constitution for the Third Order of St. Francis which not only stressed the spiritual life of the tertiaries but also placed emphasis on the importance of apostolic works.

At an early date the other mendicant orders formed third orders on the same lines as the Franciscan, and so there came into being Dominican, Carmelite, Augustinian, Servite, and Premonstratensian tertiaries, together with a large number of others.

(J. C. WE.)

**TERTIARY**, in geology, the time interval next after the Cretaceous period and before the Pleistocene. Currently it is considered as a period of the Cenozoic era (*q.v.*) as indicated on the accompanying geologic time chart, but in the past it has usually been given the rank of an era.

The name Tertiary (from the Latin *tertiarius*, "belonging to the third part") was assigned to the era by early geologists (see *Epochs and Stages of the Tertiary*, below). These pioneers perceived that the much faulted and folded beds of rock bearing comparatively few fossils, which they observed in some localities, were much older than the largely undeformed and fairly abundantly fossilized beds found elsewhere. Therefore they classified the deformed rocks, the oldest that had been observed, as Primary; and the younger rocks that in places overlay the Primary as Secondary. A third group that overlay the Secondary sequence was distinguished, and this became the Tertiary. As indicated above, the Tertiary was ranked as an era until the most recent deposits, dating from the beginning of the Pleistocene epoch, or Ice age, and including much glacial till and unconsolidated alluvium, were distinguished as the Quaternary, and both were designated periods of the Cenozoic (recent-life) era. The Secondary rocks were assigned to the Mesozoic (middle-life) era and the Primary rocks to the Paleozoic (ancient-life) era; and the oldest rocks, those older than the Paleozoic, were designated as belonging to Precambrian time.

This article deals with the evolution of life and with geologic conditions during the Tertiary and discusses the history of the study of the period and its division into epochs and stages. For general information on the place of the Tertiary in geologic time see *GEOLOGY: Historical Geology*. For more detailed information about the epochs included in this period see *PLIOCENE*; *MIOCENE*; *OLIGOCENE*; *Eocene* and *PALEOCENE*.

**Life in the Tertiary.**—Of the various organisms whose fossil remains are preserved in Tertiary rocks the mammals are most notable. During this period mammals evolved from small primitive creatures which survived the reign of dinosaurs to become the dominant vertebrates. The modifications which took place in various mammalian lines during Tertiary time are astounding, and as a result mammalian stages of evolution often provide the easiest means for world-wide correlation of Tertiary deposits.

The Paleocene was characterized by a variety of generally small primitive mammals only remotely related to modern types,

but with the beginning of the Eocene many of the more modern stems appear. Concurrently, extinction of aberrant or unsuitably phyla such as uinatheres, creodonts, titanotheres and oreodonts occurred at various times and many lines of development did not survive the Tertiary.

The diverse Tertiary fishes, both fresh water and marine, were already broadly differentiated by Cretaceous time, and subsequent development was little more than speciation. Of the various amphibians, only frogs, salamanders and the wormlike caecilians survive the period. Lizards, snakes, crocodiles and turtles are the few reptiles which survived the age of dinosaurs. Birds are sparsely represented but the known fossils show an early diversification into modern types, presumably in the late Mesozoic and early Tertiary eras.

Marine invertebrate faunas of the Tertiary show a great variety

<b>PRECAMBRIAN TIME</b>			
		Few fossils . . . . .	more than 3,490

of molluscan forms and an abundance of large foraminifera, but the once dominant ammonites are absent, although other cephalopods such as nautiloids and squids survived.

In the plant world, the greatest advances were among the flowering plants (angiosperms). Specialization of structures adapted to insect pollination, and fructifications suitable for dissemination by birds and other animals accompanied the general progress of animal evolution. See also *PALEOBOTANY*; *PALEONTOLOGY*.

**Conditions During the Tertiary.**—The end of the Cretaceous was marked in most areas by a great regression of the sea and by a shifting of the basins of deposition, generally toward the present margins of the continents. New marine transgressions were initiated in the Paleocene and lower Eocene in many parts of the world. During the Eocene, these transgressions advanced notably in most places. Tethys, the seaway extending from the western Mediterranean across to India, was finally broken up about the beginning of the Miocene. Marine transgressions during the Miocene were often as extensive as those of the Eocene, but in general the seas encroached less and less on the land in the later Tertiary.

The great mountain ranges of the western hemisphere, such as the Rocky mountains and the Andes, were established by the beginning of Tertiary time, but they had periodic rejuvenations during the period. Alpine orogeny, however, appears to have been mid-Tertiary in its expression. The coast ranges of western United States, although representing a zone diastrophically active during most of Tertiary time, assumed their present shape during the late Tertiary and Pleistocene, a history more or less applicable to other mountain chains in the great seismic belts.

Continental or terrestrial deposits of Tertiary age accumulated on all the land masses which were emergent during the period. These deposits occur in many places, but those of western United States, Argentina, western Europe, Egypt, India and

northern China are perhaps the best known and have furnished most of the known terrestrial fossils of this age.

In the early Tertiary, tropical climates extended to much higher latitudes than at present (for instance, to 50° N. or more along the western coast of North America). Subsequently the isotherms gradually retreated toward the equator, culminating in the Pleistocene ice age. The present day narrow tropical belt is abnormal and during much of geologic time the tropics were as widespread as in the early Tertiary.

**Epochs and Stages of the Tertiary.**—The name was first used and defined by Giovanni Arduino in the 18th century in a letter to Antonio Vallisneri, professor in the University of Padua, Italy. Subsequently the term was used by G. Cuvier and A. Brongniart in 1801 for deposits in the Paris basin.

The Tertiary faunas of western Europe consist, for the most part, of mollusca of modern aspect, and in 1830 Gérard Paul Deshayes determined the percentages of living species found at several horizons.

With the aid of Deshayes' percentages, the work of J. J. d'Omalus d'Hallooy in Belgium, and of Thomas Webster and William Buckland in England, Sir Charles Lyell in 1833 divided the Tertiary into three main epochs, viz., Eocene with 3½%, Miocene with 17% and Pliocene with 35% to 50% of recent species. In 1854 Heinrich Ernst von Beyrich introduced the term Oligocene for the time interval represented by deposits transitional between Eocene and Miocene. A fifth division, Paleocene, was proposed by Wilhelm Philipp Schimper in 1874 for the earliest part of the Tertiary on the basis of paleobotanical evidence.

At present the five epochs of the Tertiary are recognized not on the percentage of living species, as first defined by Lyell, but on the general character and comparative stage of development of the faunas, or on stratigraphic relationships.

Some geologists group the epochs of the Tertiary into two primary divisions, as follows:

Later Tertiary or Neogene	{ Pliocene Miocene
Earlier Tertiary or Eocene (or Paleogene or Nummulitic)	{ Oligocene Eocene Paleocene

During the Tertiary, the marine faunas became increasingly more provincial and in consequence there is much difficulty in making intercontinental correlations. Because of this, local standards have been established, notably in North and South America, Indonesia (East Indies), New Zealand and Australia. In some areas, as in the western United States there are as many as three different standards used, each primarily utilizing a different group of organisms for recognition of the intervals. As a result there are divergent correlations of the same local sequence with those of Europe (see Table I).

As proposed by Lyell, Beyrich and Schimper, the five epochs are not definitely bounded, and inasmuch as their types are found in different basins and there are certain intervals (such as the Pontian and Sarmatian) not clearly included in any epoch, a number of discrepancies have arisen in their usage and significance (see Table II).

In addition to the epoch subdivisions of the Tertiary, there early arose a series of time-stratigraphic units, or stages. This concept was first proposed by Alcide d'Orbigny in 1840 and 1842 and subsequently formed the basis for most regional correlation in Europe. Because the types of these stages are not always in the type areas of the epochs and because of the uncertain boundaries of the epochs, there is disagreement with regard to the placement of some stages.

**TERTULLIAN** (QUINTUS SEPTIMIUS FLORENS TERTULLIANUS) (c. 155–after 220), one of the greatest of the early Christian writers of the west, was born of pagan parents in Carthage. His education gave him a fair knowledge of philosophy and Greek and Latin literature and he was further trained in the law. In his youth deeply involved with the literary social life of the day, he remained for the whole of his life under the spell of the word, but his legal training left an even greater impress on his personality and his writings. He became an expert in law, though it is most unlikely that he is to be identified with the jurist Tertullianus, of whose writings the *Corpus iuris civilis* gives a few excerpts.

In mature manhood Tertullian became a Christian (c. 193). He does not give the reasons for his conversion, which took place in Rome or Carthage, but the heroism of Christians in times of persecution impressed him deeply and personal experience is probably reflected in his famous words *semen est sanguis Christianorum* ("the seed is the blood of Christians," *Apologeticum* 50). After his conversion he devoted himself to the study of Scripture and of Christian literature, and by using his knowledge of law, literature and philosophy he became the great defender of the Christian faith against the pagan state, against the Jews and against several heretic sects. According to Jerome he became a priest of the church of Carthage. His clerical status is denied by several modern scholars, but his preponderant role of teacher and the catechetical character of several of his treatises which apparently summarize sermons seem to confirm the information of Jerome, who concerning Tertullian draws on reliable tradition.

Tertullian carried on his literary activity between the years 195 and 220. His works show an ever-growing rigorism which led him to sympathize with Montanism (*q.v.*), and about 207 he openly went over to this sect. But soon he broke off from it to become the head of a small group, the so-called Tertullianists, who survived at Carthage up to the time of St. Augustine. Nevertheless Montanism did not prevent him from remaining dogmatically orthodox in most respects. His doctrine of the Trinity finds its best expression in the late work *Adversus Praxeas* (after 213), and it is in this doctrine and in Christology that he made his greatest contribution to theology. In his latest works there is a growing violence and then, after 220, his literary activity ceases altogether. Having done battle with pagans, Jews, Marcionites, Gnostics, Monarchians and Catholics he died in Carthage, according to Jerome at a great age.

The works of Tertullian, most of which cannot be exactly dated with certainty, fall into three classes: the apologetic (defending Christianity against paganism and Judaism), the polemical-dogmatic (refuting heresies and heretics) and the disciplinary, moral and ascetic works (among which those of the extreme Montanist period form a special group, already marked as such by Jerome).

**Apologetics.**—The *Ad nationes* and the *Apologeticum*, which are related to each other, both seem to have been written in 197 and both defend Christianity against paganism. The first is a mere collection of material drawn from the Greek apologists; the *Apologeticum*, directed to the governors of the Roman provinces, is a very personal work in finished form. The argumentation shows clearly the influence of the author's juridical training. It is the most famous of all Tertullian's works and it has a textual tradition of its own. In the *De testimonio animae*, written soon after the *Apologeticum*, Tertullian discusses the *testimonium animae naturaliter Christianae*: the awareness of the creator in the soul, by nature Christian, as derived immediately from the universe and as evidenced in the ordinary language of men. *Ad Scapulam* (212), an admonition to the persecuting proconsul of Africa, anticipates a topic elaborated later by Lactantius. *Adversus Iudaeos* deals with the problem of Jewish tradition and particularly with that of the Old Testament. Its main source is Justin's dialogue with Trypho. According to Tertullian the Law is abolished because the giver of the New Covenant has already appeared. Henceforth the Old Testament must be interpreted spiritually. Ch. 9–14 are merely excerpts, made by a compiler, from book iii of Tertullian's *Adversus Marcionem*.

**Polemical-Dogmatic Works.**—In *De praescriptione haereticorum* (c. 200) Tertullian again makes the most of his knowledge of law. His aim was to end the controversy between Catholics and all heretics by advancing the technical argument of the *praescriptio*, a legal objection leading to rejection of a cause. According to Tertullian the heretics cannot use Scripture because it is not theirs; the gospel is the possession of the church, handed down to it by apostolic tradition. Other treatises deal with single heresies. In *Adversus Marcionem*, the major source for knowledge of the heresy of Marcion, Tertullian draws on Justin, Irenaeus and probably on a treatise by Theophilus of Antioch. *Adversus Hermogenem*, directed against the doctrine of Hermogenes, a painter living in Carthage according to whom God had created the universe out of preexisting matter, gives an explanation of the Christian teaching on creation. *Adversus Valentinos*, dealing with the Gnostic sect of the Valentinians, depends on the first book of Irenaeus' great work against heretics. The *Scorpiae* is a defense of martyrdom against the Gnostics, who are compared to scorpions.

*De carne Christi* and *De resurrectione carnis* are closely connected; both deal with the resurrection of the body, which was denied by pagans, Sadducees and heretics. In *De carne Christi* Tertullian proves, against Docetism, that Christ was really born, that he truly lived, died in human flesh and rose from the dead. He defends the Virgin's true and real motherhood and stresses the human nature of Christ by maintaining that he was ugly. This treatise paves the way to *De resurrectione carnis*, which refutes those who denied the resurrection of the flesh. The *Adversus Praxeas* (213), already mentioned, is directed against the Trini-

tarian doctrine of Praxeas. In it the term *trinitas* occurs for the first time. It is the most important contribution to the doctrine of the Trinity in the ante-Nicene period, though it is not free from subordinationism. *De anima* (c. 213) is a refutation of heretical doctrines about the soul, which leads Tertullian into controversy with pagan philosophy. It contains not a well-thought-out system of psychology but a series of theories of polemical intentions. Tertullian's chief thesis is the corporeality of the soul; he also advocates traducianism (see CREATIONISM AND TRADUCIANISM). His chief source was the pagan physician Soranus.

**Disciplinary, Moral and Ascetic Works.**—*Ad martyras*, a short address to a number of Christians (or catechumens) who were in prison awaiting martyrdom, dates probably from 197; that the famous martyrs Perpetua and Felicitas belonged to the group cannot be proved, and it is also uncertain whether Tertullian is the editor of their *Passio*. The *De spectaculis* (197 or 202) is a condemnation of all public games. In *De cultu feminarum* (between 197 and 201), Christian women are warned not to be dominated by pagan fashion. Three treatises, *De baptismo*, *De oratione* and *De paenitentia*, written between 200 and 206, all of them addressed to catechumens and similar in composition and tone, can be considered as a trilogy. The first, particularly important for the history of the baptismal rite, is the only ante-Nicene treatise on any of the sacraments. *De oratione*, which gives the earliest exposition of the Lord's Prayer in any language, deals with the interior and exterior discipline of prayer. *De paenitentia* is important for the history of ecclesiastical penance. *De patientia*, of the same period, sheds light on Tertullian's personality.

*Ad uxorem*, composed between 200 and 206, gives suggestions which his wife is to follow after his death. In the first book he admonishes her to remain a widow, in the second he discusses the possibility of remarriage: if she wishes to remarry it must be to a Christian. In *De exhortatione castitatis*, written some years later, he again takes up the problem of second marriage, which he now rejects as contrary to the will of God. In *De virginibus velandis* (c. 208) he returns to the idea which he had already formulated that women, whether married or unmarried, should be veiled. *De corona* (211), written in defense of a soldier who refused to wear a wreath, discusses a far more important problem: that of the participation of Christians in military service. The same problem, but in a larger framework, that of the behaviour of Christians in the pagan world, is discussed in *De idololatria* (211); the Christian must abstain from everything that is in any way connected with idolatry.

Tertullian's last works are characterized by Jerome as a sort of libel in which he discusses the controversies which brought about his rupture with the church. To this group belong *De monogamia*, *De fuga*, *De ieiunio* and *De pudicitia*. In *De monogamia* (213) the third of Tertullian's treatises on marriage, he regards second marriage as illicit and almost adulterous. In *De fuga* (212) he holds—in opposition to his previous views—that to take refuge in flight during persecution is against the will of God. *De ieiunio* is a fierce attack on the Catholic rejection of the Montanist practices of fasting. In *De pudicitia* he attacks the church again, this time in the field of penitential discipline, dealing particularly with the power of the keys. The *De pallio* is a small and bizarre tract, full of wit and sarcasm, in which Tertullian explains why in everyday life he substituted the mantle (*pallium*), the traditional garb of philosophers, for the Roman toga. The work is a sort of literary tour de force and the reader wonders if it is to be taken seriously. The change of dress coincides either with Tertullian's conversion or with his separation from the Catholic Church.

**Style and Influence.**—Tertullian was the first Christian theologian to leave behind an extensive collection of works written in Latin. With him early Christian Latin literature made a magnificent start. Though he was certainly not the creator of early Christian Latin, a distinction which has erroneously been claimed for him, he was the first to introduce the special idiom of Latin-speaking Christians into literature. In style he is inspired by the Asiatic manner, the fashionable "modern" style of his day, which preferred short paratactical sentences, adorned with all

sorts of play on sounds and words, to the long classical periods. His style is highly personal, often pregnant and terse and not free from obscurity, though at the same time powerful and passionate.

Tertullian never even tried to create a theological system, but he often found formulas and definitions which were clear and precise, particularly in his doctrine of the Trinity. Some of his formulas are identical with those of the Council of Nicaea (325), and in his Christology he anticipates the Chalcedonian definition (451). All his works bear the stamp of his juridical training, not only in language and style, but even more in his way of thinking. His juridical training supplied him his major argument against heresy, the *praescriptio*; the way in which he deals with the relation of God and man is equally inspired by his juridical training, words such as debt, satisfaction, guilt, compensation, occurring regularly. Law also inspired his defense of the Christians against the state. He exercised great influence on Christian thought, particularly (in the view of many, though not all, scholars) through Cyprian, who sifted the thoughts he had given, rounded them off and turned them into current coin, always aware of his dependence on Tertullian, whom he designated as his master.

See also references under "Tertullian" in the Index.

**TERUEL**, a town in northeastern Spain, and capital of the province of the same name, is on the left bank of the Guadalquivir River at its confluence with the Alfambra, and on the Calatayud-Sagunto railway, about 70 mi. (113 km.) NW of Valencia. Pop. (1960) 19,776 (mun.). The older part of Teruel has remains of its old walls and the towers which fortified them, narrow streets and crumbling medieval houses, but modern suburbs have been built outside the walls. In the cloisters of San Pedro lie the remains of the celebrated "lovers of Teruel," Diego Juan Martínez de Marcella and Isabel de Segura (13th century). Their story is the subject of works by Tirso de Molina, Juan Pérez de Montalbán, Juan Eugenio Hartzenbusch, and—in an Italian setting—by Boccaccio. Structures from the 16th century include the cathedral and an aqueduct built by Pierre Bedel. Teruel was the scene of fierce fighting in the Civil War (1936-39).

**TERUEL PROVINCE** (area 5,715 sq.mi. [14,803 sq.km.]; pop. [1960] 215,183). Three-quarters of the province is covered by mountains, mainly Cretaceous, belonging to the Iberian System, the highest ranges being the Sierra de Albarracín and the Montes Universales, both in the southwest near the border of the province of Cuenca. Heavy snow falls in the mountainous region every winter, and most of the waters flow into the Ebro River. In the northeast, where a plain runs northward into the province of Zaragoza, a Catalan dialect is spoken.

Alcañiz (pop. [1960] 10,035) is the second largest town in the province, most of the others containing less than a quarter of its population. Some of the festivals in the smaller towns are of great antiquity. At Castellote, a festival called the Romería del Llovedor, or Rain Procession, is celebrated by the men in May and by the women on Whit Monday. At Híjar hooded penitents wander round the streets beating drums from Thursday to Saturday in Holy Week.

Marble and chalk are quarried, and the chief products include corn, wine, oil, cheese, fruits, timber, flax, hemp, silk, and wool.

(C. D. L.)

**TERZAGHI, KARL** (1883-1963), U.S. civil engineer who established soil mechanics (*q.v.*) as one of the basic subjects of civil engineering science, was born in Prague, Czech., on Oct. 2, 1883. He served in the Air Corps of the Austrian Army during World War I and then joined the staff of Robert College (American), in Istanbul, Turk. Although much work on foundations,

earth pressure, and stability of slopes had been done earlier, Terzaghi, as a result of research during the period 1919-25, provided the unifying concepts that made soil mechanics a science. These were published in *Erdbaumechanik* (1925). Following this he spent four years in the United States, where he obtained widespread recognition as a teacher, research worker, and consulting engineer. From 1929 to 1938 he held the newly created chair in soil mechanics at the University of Technology in Vienna and then served as professor of civil engineering at Harvard University from 1946 until his retirement in 1956, though he served there as consultant and lecturer until his death. Terzaghi was president of the International Conference of Soil Mechanics and Foundation Engineering from its inception in 1936 until 1957. His consulting practice was worldwide, and he wrote more than 200 scientific papers. He died in Winchester, Mass., on Oct. 25, 1963.

(A. W. Sk.)

**TERZA RIMA** ("third rhyme"), the name given to a verse form, Italian in origin, consisting of a series of stanzas (*terzine*, tercets) each of which has three hendecasyllabic (11-syllable) lines. The first and third lines rhyme with one another, and the second rhymes with the first and third of the following tercet. The series ends with a line which rhymes with the second line of the last stanza, so that the rhyme scheme is: *aba, bcb, cdc, ded, efo* . . . , *yzzy, z*.

Dante, in his *Divina Commedia* (c. 1307-21), was the first to adopt the metre for a long poem, and it became known as *terzina dantesca*. Its essential elements are usually traced back to a particular form of the troubadour *serventes*, consisting of a series of stanzas of three monorhyme lines, followed by a five-syllable line rhyming with the stanza following. It is possible, however, that Dante may have developed the metre from the tercets from which the sestet of the Italian form of the sonnet (*q.v.*) is composed.

After Dante, *tersa rima* was widely used in Italy in the 14th century, especially for allegorical and didactic poetry (Petrarch's *Trionfi*; Boccaccio's *Caccia di Diana*, *Ninfale d'Ameto*, *L'Amorosa Visione*; Fazio degli Uberti's *Dittamondo*; etc.), and it was well used in the 15th century by Lorenzo de' Medici. In the 16th century it was used for satire and burlesque, notably by Ariosto and Francesco Berni, and it became the typical form for satire. At the end of the 18th century Vincenzo Monti revived its use for epic and allegory, but since then it has been only occasionally used, for lyric and elegiac poetry.

Outside Italy, *tersa rima* has not been widely adopted. Sir Thomas Wyatt experimented with it in the early 16th century, and later examples of its use in English are provided by Samuel Daniel, Shelley, Byron, Elizabeth Barrett Browning, and Longfellow. In France it was introduced in the 16th century, and revived in the 19th, notably by Théophile Gautier.

See M. Fubini, *Metrica e Poesia: Lezioni sulle forme metriche italiane*, vol. I (1962).

**TESCHEN** (Polish CIESZYN, Czech TESIN), a province divided between Poland and Czechoslovakia in 1920, which had been originally one of the Polish Silesian principalities. It became part of the Bohemian crown in 1335, passing with that crown to the Austrian Habsburgs in 1526; after the death of the last Piast prince of Cieszyn in 1625, the principality was administered in an Austrian *Kronland*.

On the eve of World War I Teschen Silesia covered 881 sq.mi. (2,283 sq.km.). According to the Austrian census, its population rose between 1880 and 1910 from 262,412 to 426,667. The latter total comprised 233,850 Poles (54.8%), 115,604 Czechs (27.1%), and 76,916 Germans (18.1%). The increase in population was explained by rapid industrialization, the area being particularly rich in coking coal.

Soon after the collapse of Austria-Hungary, the two regional political organizations, the Polish National Council and the Czech National Committee, established on Nov. 5, 1918, a frontier on an ethnic basis. The Prague government refused to recognize the agreement, claiming the whole of Teschen Silesia on historic grounds. On Jan. 23, 1919, Czech troops attacked the small Polish garrisons and occupied the major part of the disputed territory.

On Feb. 5 an armistice was concluded, cutting the area in two almost equal parts. On Sept. 27 the Allied Supreme Council decided to hold a plebiscite, which, however, was never held because of Czech opposition. In July 1920, when the Russo-Polish War (*q.v.*) took an unfavourable turn for Poland, Władysław Grabski, the Polish prime minister, was forced at Spa, on July 10, to agree to a partition of Teschen Silesia by the Allies without a plebiscite. (See SPA, CONFERENCE OF.) Partition was determined by the Paris Conference of Ambassadors on July 28, with Czechoslovakia obtaining 491 sq.mi. (1,272 sq.km.). While the Czech part, which comprised the industrial basin, included about 140,000 Poles, there were practically no Czechs in the Polish part.

In September 1938, at the time of the Munich Conference, the Polish government asked the Czechoslovak government for treatment of the Polish population in the Czech part of Teschen Silesia on the same terms as the other national minorities within Czechoslovakia. President Edvard Benes of Czechoslovakia accepted on Sept. 22 "the principle of frontier rectification." On Oct. 1 a new Polish-Czechoslovak frontier, practically identical to that of Nov. 5, 1918, was established.

After World War II Władysław Gomułka, Polish deputy premier, declared in Moscow on June 26, 1945, that Teschen Silesia was "historically and ethnically Polish," but Poland would accept a territorial settlement with Czechoslovakia based on the principle of self-determination. Zdeněk Fierlinger, the Czechoslovak premier, refused to discuss any cession of the territory attributed to Czechoslovakia on July 28, 1920. Under Soviet pressure that frontier line was restored. (For the town of the same name see CIESZYN.)

See R. Fitzgibbon Young, "The Teschen Question," in H. W. V. Temperley's *History of the Peace Conference of Paris*, vol. iv (1921); B. Kożusznik, *The Problem of Cieszyn Silesia* (1943). (K. SM.)

**TESIN:** see CIESZYN.

**TESLA, NIKOLA** (1856–1943), U.S. inventor of electrical devices and equipment who introduced the first practical applications of alternating current, was born July 9, 1856, at Smiljan, Croatia (Yugoslavia). He attended the polytechnic school at Graz, specializing in physics and mathematics, and finished his studies at the University of Prague in 1880. Four years later he went to the United States and for a time was with Thomas Edison's company. He then established the Tesla laboratory in New York city and devoted his efforts to research.

Tesla conceived the rotating magnetic field principle as an effective method of utilizing alternating current for power. He patented the induction, synchronous and split-phase motors, and new forms of generators and transformers; this equipment formed the system for the generation and use of power from Niagara falls. By means of lectures in Europe and the United States beginning in 1891, he announced discoveries and applications of high-frequency alternating current, including the high-frequency resonant transformer, or "Tesla coil." Tesla died in New York city, Jan. 7, 1943.

The 100th anniversary of his birth was commemorated by scientific institutions throughout the world, and the unit of magnetic flux density in the MKS system was named the "tesla" in his honour.

See John J. O'Neill, *Prodigal Genius: the Life of Nikola Tesla* (1944); The Nikola Tesla Museum, *Nikola Tesla, 1856–1943; Lectures—Patents—Articles* (1956). (L. I. A.)

**TESO** (ITESO), a Nilo-Hamitic people of central Uganda, numbered about 525,000 in the 1960s; there were also about 42,000 in western Kenya, known as Iteso; they are closely related to the Kumam of Uganda (62,000), and also to members of the Karamojong tribal cluster of eastern Uganda.

Unlike most Nilo-Hamites (*q.v.*), the Teso are sedentary cultivators, keeping some cattle; they grow much cotton and are counted among the most progressive farmers of Uganda. Much of their traditional culture and organization was lost through suppression by the conquering Ganda (*q.v.*) under Kakunguru at the end of the 19th century. The age set (*q.v.*) and the clan lost their importance, and much of the indigenous territorial organization was destroyed. The basic local group is the *etem*, a

small settlement that may comprise several hamlets; today the term is applied to the subcounty, an administrative subunit of one of the six counties, each under a government-appointed chief. The homesteads of a hamlet are usually those of the men of an extended family based on a three- or four-generation patrilineal descent group. Genealogical ties are rarely reckoned beyond this range. There are also vaguely defined patrilineal clans dispersed throughout Teso.

Although age sets no longer function as groups, it is known that they were generally arranged in a permanent recurrent cycle of seven or eight names; each set was related mystically to some aspect of nature (e.g., the floods age set dealt with the ritual of fishing). Almost all indigenous religion has been replaced by Christianity; previously Teso believed in an omnipotent but remote god, Akuj, and in a god of calamity, Edeke.

**TESSIN, CARL GUSTAF**, COUNT (1695–1770), Swedish court official, statesman, collector and writer, helped to create a modern Swedish prose style, and his poems and fables can still be admired. He was born in Stockholm on Sept. 5, 1695, the son of the great architect Nicodemus Tessin the Younger (1654–1728). After studies in France and Italy he was employed on his first diplomatic missions before succeeding, in 1728, to his father's post of superintendent of the court and to the task of completing the new Stockholm castle according to his father's design. This he did with help from Carl Hårleman and from foreign artists (mostly French), who also helped him to set up a Swedish Academy of the Fine Arts.

Though he stood for aristocratic government against royal absolutism, Tessin admired Charles XII and became a founder of the Hat party in the hope that its policy would regain some of the provinces lost in the Great Northern War (see SWEDEN: History). He was elected *lantmarskalk* in 1738 by a large majority but failed to prevent his party from starting war against Russia in 1741 without guarantees of foreign aid. After the peace of Åbo (1743), however, he cleverly extricated Sweden from "the Russian bear-hug." Adolphus Frederick (*q.v.*), Russia's nominee as heir to the Swedish throne, was married to the imperious Prussian princess Louisa Ulrica in 1744; Tessin formed a strong friendship with her, and they finally induced Adolphus Frederick to conciliate Denmark by renouncing his hereditary interest in Schleswig-Holstein. Tessin was appointed tutor to the prince Gustavus (born in 1746) and head of the chancellery, but he lost Louisa Ulrica's friendship by insisting on a marriage contract (1751) between Gustavus and a Danish princess instead of her Prussian niece. His letters of advice to Gustavus were printed at the expense of the diet (1751 and 1753) during its struggle against the crown and won European fame as models of educational writing, but he had to resign the chancellery in 1752 and the tutorship in 1754.

When he withdrew from public affairs (1761), he found himself desperately short of money in his retirement at Åkerö, and the books and the works of art on which he had spent his personal fortune were sold. Later he was formally reconciled to the royal couple, thanks to Gustavus. He died at Åkerö, on Jan. 7, 1770. He left voluminous diaries, and many of his private letters survive.

**TEST ACTS**, in England, Scotland, and Ireland, provided that none but those who professed the established religion were to be eligible for public office. In England discrimination against Roman Catholics and Nonconformists did not take this particular form until the reign of Charles II, chiefly because, until this comparatively tolerant period, the severity of the laws against recusants, whether Catholic or Nonconformist, precluded the possibility of their being so employed. In Scotland legislation followed soon after the Reformation, while in Ireland the support given to James II until his defeat at the Battle of the Boyne in 1690 led to the introduction of tests designed to exclude dissenters from almost all branches of public life.

The form that the test took in England was to make the receiving of Holy Communion according to the rites of the Church of England a condition precedent to the holding of public office. It

was first embodied in legislation in the Corporation Act of 1661 (one of the acts in the so-called Clarendon Code) which enacted that, in addition to taking the oaths of allegiance and supremacy and subscribing a declaration against the Solemn League and Covenant, all members of town corporations were within one year before election to receive the sacrament of the Lord's Supper according to the rites of the Church of England. The immediate occasion of the extension of this principle to all public offices was the king's declaration of indulgence (March 1672) dispensing with the laws inflicting disabilities on all Nonconformists or recusants: Parliament reacted by passing the first Test Act, of 1673, to which Charles was compelled to consent. This act provided that all persons holding any office, civil or military, were to take the oaths of supremacy and allegiance and to subscribe a declaration against transubstantiation, and were, in addition, to receive the sacrament within three months after admittance to office. This act, which did not apply to peers, was followed by a second Test Act in 1678, to the effect that all peers and members of the House of Commons should make a declaration against transubstantiation, invocation of saints, and the sacrifice of the Mass; an exception being made in favour of the heir presumptive, James, duke of York.

Both Charles II and James II circumvented this legislation by use of the dispensing power, afterward abolished by the Bill of Rights (1689). Throughout the 18th century there were amendments to, and partial repeals of, the Test Acts, and a number of acts of indemnity to relieve those who had committed breaches of them from the consequences, but repeal had to wait until the 19th century. An act of 1828 removed the necessity of taking the sacrament as a qualification for office, and the Roman Catholic Emancipation Act of 1829 abolished the requirement of oaths and declarations against transubstantiation. Formal repeal of the Corporation Act and the Test Acts of 1673 and 1678 followed in acts of 1871, 1863, and 1866, respectively, while in 1871 religious tests were abolished in the universities except for degrees and professorships in divinity and certain kindred subjects.

In Scotland, the form of the legislation was different in that the taking of communion formed no part of the test. An act of 1567 made profession of the reformed faith a condition of public office, and a further Test Act was passed in 1681 but abolished in 1690; and in the 18th century the legal disabilities were confined to those engaged in education. All tests were abolished in 1889.

In Ireland, on the other hand, the principle of using the sacrament as a test was adopted by an act of 1704, which followed earlier legislation exacting oaths of allegiance and declarations against Roman Catholic beliefs and practises from peers, members of the House of Commons, bishops, and members of both branches of the legal profession; English legislation on oaths and declarations was adopted by Yelverton's act in 1782. All these provisions were abolished by the Promissory Oaths Act (1871).

Article VI of the Constitution of the United States prescribes that "no religious test shall ever be required as a qualification to any office or public trust under the United States." A similar provision is included in most state constitutions. (W. T. Ws.)

**TESTAMENTUM DOMINI** (TESTAMENT OF OUR LORD), one of a series of writings, claiming to embody the fundamental rules of the early Christian Church, others of which were the *Apostolic Constitutions* and the *Apostolic Tradition* of Hippolytus (see CONSTITUTIONS, APOSTOLIC; HIPPOLYTUS, CANONS OF SAINT). It falls into three distinct parts: an apocalyptic introduction (book i, ch. 1-18; the division into books, however, was clearly not original); a church order proper (i, 19-ii, 24); and a conclusion (ii, 25-27) of the same apocalyptic character as the introduction.

The testament has several distinctive characteristics. First and foremost is its ascription to the Lord himself, an attempt to claim the highest possible sanction, higher than that claimed by the various compilations styled "apostolic." This fact alone indicates the preexistence of certain of the latter. Again, the whole tone is one of highly strung asceticism, and the regulations, by their severity, point to a small and strictly organized body. They are "the wise," "the perfect," "sons of light"; but this somewhat Gnostic terminology is not accompanied by any signs of

Gnostic doctrine, and the work as a whole is orthodox in tone. They are set in the midst of "wolves," despised and slighted by the careless and worldly: there is frequent mention of "the persecuted" and of the duty of "bearing the cross." Charismata, and above all exorcisms, occupy a very important place. There is a vivid realization of the ministry of angels, and the angelic hierarchy is very complete. Great stress is laid upon virginity (although there is no sign of monasticism), fasting, and regular attendance of the whole clerical body and the "more perfect" of the laity at the hours of prayer.

The testament was originally written in Greek, probably in the 4th-5th century; it survives only in a 7th-century Syriac translation (*editio princeps* by Ignatius Ephraem II Rahmani, 1899, with Latin translation).

See James Cooper and A. J. Maclean, *The Testament of Our Lord*, Eng. trans., with introduction and notes (1902); and *Dictionnaire de théologie catholique*, vol. xv, col. 194-200 (1946). (W. E. Co.; X.)

**TETANUS** (LOCKJAW) is an acute infectious disease caused by a bacillus and the poison it elaborates in human tissues. It is characterized by muscular rigidity and spasms. The almost constant involvement of the muscles of the jaw accounts for the popular name of the disease.

**History.**—Although a comparatively rare disease, tetanus has been recognized for centuries, as is shown by the picturesque descriptions of the disease by Hippocrates (5th-4th century B.C.), Aretaeus (2nd century A.D.), and John of Arderne (14th century); the observation of its occurrence from such trivial injuries as the bite of a tame sparrow, noted by G. B. Morgagni (18th century); and the concern of Joseph Lister (19th century) over tetanus among hospital patients. Landmarks of tetanus research in modern times included the recognition of the infectious nature of the disease, by A. Carle and G. Rattone, A. Nicolaier, and others, 1884-88; isolation of the bacillus and its toxin by S. Kitasato, T. Weyl, and A. Nicolaier, 1889-92; animal experiments on both active and passive immunization by S. Kitasato, E. von Behring, W. Schütz, and L. Vaillard, 1890-92, and the application of experimental results to veterinary and human medical practice by many workers; crystallization of the neurotoxin (see below) by L. Pillemer and K. C. Robbins, 1949; and the development of improved methods of treatment by L. Eckmann, 1960.

**Cause.**—The bacillus of tetanus, *Clostridium tetani*, is a slender rod visible with the conventional microscope. It occurs in the dormant (spore) and vegetative, toxin-producing forms. Conversion of the spore into the vegetative form occurs under conditions of oxygen deprivation; i.e., various levels of the anaerobic state. Although ten different strains of *Clostridium tetani* have been identified, it is fortunate that the neurotoxins of all ten strains can be completely neutralized by a single antitoxic serum.

The vegetative forms, which elaborate the poison, are destroyed as easily as the vegetative forms of other bacteria. The spores, however, show variable degrees of resistance to thermal and chemical agents; e.g., they are killed in 1 hour by dry heat but in 5 minutes by live steam (autoclaving), or in 12 to 15 hours by 5% carbolic acid but in 2 to 3 hours by 1% bichloride of mercury. Animal experiments by A. A. Anwar and T. B. Turner (1956) indicated that penicillin and the tetracycline compounds (principally terramycin) are lethal for the bacillus, mainly in the vegetative forms; not all authorities are willing to rely solely on antibiotics as preventive agents against tetanus.

Protected from sunlight and other adverse environmental conditions, the spores may survive for a number of years—possibly almost indefinitely. The spores are distributed widely in nature, mainly in the superficial layers of the soil. In general, the degree of soil pollution parallels the amount of fecal contamination from natural or artificial manuring or from human excreta.

The most important predisposing cause of tetanus is a wound which permits entrance of spores of *Cl. tetani* into tissue of a susceptible host. The wound may be trivial or severe, varying from simple superficial abrasions to severe lacerations. Not infrequently the source of infection may be obscure (cryptogenic tetanus).

Both the occurrence and the severity of tetanus are governed by the amount of poison elaborated by the organism and absorbed by

the body, and the resistance of the host. Although a definite spectrum of resistance to the neurotoxin among lower animals is documented, natural immunity does not occur in human beings. Hence, in the absence of artificially acquired protection (*see below, Control*), conditions favourable to implantation and growth of *Cl. tetani* determine the occurrence and course of the disease, which can be rendered less severe by artificially induced immunity or by nonspecific treatment; *i.e.*, antibiotic medication, sedative drugs, general care, and miscellaneous measures. Race, geographical location, sex, age, occupation, and the like are significant only insofar as they are related to environmental conditions which either facilitate or impede the development of tetanus.

Tetanospasmin, the neurotoxic component of the toxin elaborated by *Cl. tetani*, is one of the deadliest poisons known to man. It is transported from the local focus of infection (portal of entry) to the ganglion cells of the anterior horns of the spinal cord, which are then stimulated. The neurotoxin is believed to act on the synthesis and liberation of acetylcholine, a substance having a key role in the synaptic transmission of nerve impulses throughout the body. The clinical expression of central nervous system stimulation consists of fairly constant rigidity, local or generalized, frequently and unpredictably punctuated by tonic spasms. The muscles most intensively activated are those that oppose gravity; *i.e.*, the extensor groups of the limbs and neck and the masseters, which close the jaw. Local tetanus, confined approximately to the zone of injury, may occur as a precursor to generalized tetanus or as an isolated manifestation of the disease.

The period of incubation (interval between the entrance of spores and the appearance of clinical tetanus) is related to the rate of release of toxin from the portal of entry. In about 20% of civilian hospital cases the incubation period is 2 to 5 days, in 60% it is 6 to 15 days, and in the remainder it is 16 to 85 days. The region of a wound has no proved relationship to the incubation period. The prophylactic use of antitoxin may prolong the period. Statistically, the length of the incubation period is inversely related to the fatality rate; *i.e.*, the longer the period the more likely the recovery. Moreover, the speed with which the disease becomes generalized in the individual patient is important in the ultimate outcome: the slower the onset of generalized symptoms, the better the outlook.

**Symptoms and Course.**—Tetanus may be local or general; when general, it may be mild, moderate, or severe. In local tetanus the stiffness and spasms may be restricted to the muscles near the wound. When the injury occurs in the head or neck (cephalic tetanus), one or more cranial nerves may be paralyzed. If the patient survives, the paralysis gradually disappears. When tetanus is general it is usually symmetrical (involving both sides of the body in equal degree). Sometimes, however, this pattern of symmetry is violated (unilateral, abdominothoracic, or limb tetanus), with spasticity limited or more pronounced on one whole side of the body, in the muscles of the abdomen or thorax, or in one or more limbs, and occasionally without stiffness of the jaw.

Early complaints may be difficult to evaluate by examination; but when the disease process becomes more pronounced, alterations in physical behaviour, ranging from mild to severe, are encountered. In general, the main symptoms of tetanus are quite characteristic. They are:

1. Rigidity of the body musculature. This is expressed by stiffness of the jaw (trismus), a fixed spastic sardonic smile (risus sardonicus), difficulty in swallowing, backache, rigid abdominal wall, tight thorax (with the volume at its maximum—a fact of basic importance in treatment), fixed extremities, rigid neck (sometimes with a backward retraction), and spasms of the muscles of the bladder and bowel, causing retention of the urine and constipation.

2. Muscular spasms. These occur at unpredictable intervals, in various degrees of severity from mild contractions to alarming episodes associated with excruciating pain, fractures of the spinal vertebrae, brain hemorrhages, and even sudden death of the patient.

Accessory signs and symptoms are profuse drenching perspiration and overactive tendon reflexes. The mind remains clear and

the temperature normal (in the absence of certain complications).

Complications include pneumonia, collapse of one or more lung lobes, suffocation from severe muscular spasms, brain hemorrhages, injuries to the teeth, tongue, or mouth from convulsions, starvation, dehydration, fractures of the spine, fever of varied origin, pulmonary embolus with sudden death, perforated peptic ulcer, and undesirable effects from therapy; *e.g.*, serum sickness (early or delayed; *see* SERUM THERAPY), and coma from the intensive use of sedative drugs designed to prevent convulsions and suffering.

The onset and course of tetanus is sometimes erratic. For example, the classical stiff jaw may be late in appearance or even absent. Likewise, marked modifications, with associated difficulties in diagnosis, may reflect the attenuating effect of antecedent or immediate immunization measures (serum or vaccine).

**Treatment.**—Tetanus treatment employs antitoxic serum (preferably of human origin in order to avoid the serious hazards of serum sickness), sedative and relaxant drugs, compounds to control secondary infections (penicillin, tetracyclines, and allied medication), surgical procedures as required to avoid suffocation from laryngeal obstruction (tracheotomy), conservative but adequate care of wounds, measures to prevent water and chemical imbalance (dehydration and acidosis), maintenance of adequate caloric balance to avoid malnutrition, and continuous expert medical and nursing care. The creation of special tetanus treatment centres has been recognized as a critical step in the direction of minimizing the case fatality rate.

A definite statistical reduction of mortality followed the introduction of serum treatment of tetanus: from 90 to 70% among patients with short incubation periods (1–5 days) and from 70 to 29% among patients with longer incubation periods (5–10 days) (H. Zinsser, 1960). The importance of sedation and nursing care is reflected in the low death rate of 23% among a group of patients treated without tetanus antitoxin (J. Bryant and H. D. Fairman, 1940). Treatment combining drug-induced paralysis with the use of a respirator has lowered the death rate to 9% (L. Eckmann, 1960). In general, however, the mortality from tetanus is estimated at 40–50%. Danger of death is much higher in tetanus of the newborn, approaching 100% in some parts of the world.

The outlook in individual cases is best where the patient is in good health, is free of severe convulsions or complications (especially all forms of serum sickness), has only slight difficulty in swallowing, has a mild form of the disease (as evidenced by a long incubation period and slow generalization of symptoms), is neither very young nor aged (the periods when mortality is highest), has mild wounds, and obtains expert treatment. In the average case two or more weeks are required for recovery. Sometimes sudden and unexpected death occurs during apparently healthy convalescence. Occasionally the disease lasts for months or several years. With the exception of certain complications, *e.g.*, compression fractures of the vertebrae, recovery from tetanus is complete. No matter how seriously ill the patient may have been, the mind is perfectly clear after the disease has run its course. Unfortunately, tetanus may occur more than once in the same individual; therefore active immunization with tetanus toxoid must be instituted at an appropriate time interval following recovery. An attack of tetanus never of itself confers immunity.

**Control.**—The three basic factors in the control of tetanus are: (1) control of the environment to reduce opportunities for infection; (2) proper treatment of wounds; and (3) protection with tetanus antitoxin or tetanus toxoid, or both.

Environmental control has definite but limited possibilities. Accident control among children and adults, proper obstetrical procedures and care of the newborn, careful supervision in the manufacture of suture material (especially catgut) and therapeutic serums, avoidance of airtight dressings over smallpox vaccinations, and avoidance of the hazards of firecrackers, blank cartridges, bullets, and burns have significantly reduced the incidence of tetanus.

Proper treatment of wounds is essential to avoid local infec-

tion, death of tissue, and the associated formation of anaerobic environments in the body—factors favourable to the development of tetanus. Adequate cleansing, removal of devitalized tissue and foreign bodies, avoidance of injury to both healthy and disturbed structures, proper use of available antibacterial agents (penicillin and the tetracycline compounds), and immobilization of injured parts constitute a five-point program for the prevention of tetanus.

Tetanus antitoxin (antitetanic serum) for rapid protection is available throughout the world. For widespread use it is prepared from the blood serum of horses or cows that have been inoculated with tetanus toxoid or tetanus toxin, or both, and have become immune. On a limited scale, tetanus antitoxin of human origin (human tetanus-immune globulin) is available for special indications, such as allergy to animal serums; its universal use would result in a minimal incidence of all forms of serum sickness. The serum is concentrated and standardized in terms of an arbitrary unit. It must pass routine tests for safety before it is released for clinical use.

Tetanus toxoid, which stimulates active immunity in the person receiving the injection, is available either alone or combined with a variety of vaccines (diphtheria, whooping cough, typhoid, poliomyelitis, etc.). It is prepared by chemical alteration of the toxin, followed by tests to ensure absence of toxicity and to determine its potency.

Passive protection with tetanus antitoxin is desirable in all cases of injuries considered likely to be contaminated with spores of *Cl. tetani*. Active protection with tetanus toxoid is a relatively slow process which requires weeks or sometimes months for optimal development. Everyone should be actively protected against tetanus. This is especially true because a significant number of tetanus cases occur under conditions which are not controllable by routine serum (antitoxin) prophylaxis. Moreover, active protection of women in the childbearing period of life would result in temporary passive protection of newborn infants. Institution of this procedure on a large scale among primitive peoples would minimize the incidence of the highly fatal tetanus of the newborn.

Although tetanus respects no age, sex, economic status, or occupation, certain groups are considered more in need of routine active immunization than are others. They include the armed forces, civilian populations in danger of military attack, allergic individuals, farmers, industrial workers, childbearing women in localities with high incidence of tetanus of the newborn, and infants and children.

When tetanus antitoxin of animal origin (equine or bovine) is used, a detailed list of precautions against serum sickness must be obeyed. With the use of tetanus antitoxin of human origin these precautions may be largely ignored. The dose of antitoxin must be adequate; recognition of the inadequacy of time-honored doses has led to the recommendation of at least 5 to 15 times the amount used in World War I. Of vital importance is awareness of the enhanced protection conferred by antitoxin of human origin, one unit of which is estimated as equivalent to 100 units of foreign (bovine or equine) serum (J. C. Suri and S. D. Rubbo, 1961).

Tetanus toxoid is employed to build active immunity against future exposure to the disease. It does not confer immediate protection after the manner of tetanus antitoxin. Tetanus toxoid is injected in a series of two, and preferably three, doses, with appropriate intervals between the inoculations. Ordinarily, adequate protection emerges within a week after the second or third injection. At almost any time after completion of the original series of injections, very minute doses of toxoid can evoke very rapid, high, and prolonged elevations of antitoxin in the patient's body. Allergic reactions to tetanus toxoid are rare.

In patients not previously protected with tetanus toxoid, antitoxin must be employed to afford immediate protection. If the smaller doses of antitoxin (up to 5,000 units) are used, the first toxoid injection may be started at the time of the antitoxin inoculation, but at another site; subsequent doses of the toxoid are given according to routine schedule. With larger doses of antitoxin, however, the first dose of toxoid must be timed to coincide

with maximal elimination of antitoxin, since large amounts of antitoxin neutralize the effects of toxoid. The higher the dose of antitoxin, the longer the interval for the initial dose of toxoid. When tetanus antitoxin of human origin is given in the small amounts needed for protection, toxoid may be injected simultaneously, at the customary distant separate site.

In civilian practice a reliable history of toxoid inoculation validates the routine use of tetanus toxoid in the event of injuries considered possibly conducive to the development of tetanus. In military practice, however, certain evidence indicates the possible need for combined toxoid-antitoxin prophylaxis, although the reliability of tetanus toxoid alone has also been documented. In civilian practice the sole established indication for supplementary antitoxin is the factor of delay in administration of a booster dose of toxoid. The length of the delay is governed by the nature and severity of the wound.

The value of tetanus antitoxin was first demonstrated in World War I, following the introduction of prophylactic passive immunization in the British Army toward the end of 1914. The reliability of tetanus toxoid in veterinary medicine was proved in France, where the active immunization of horses began in 1925. In human medicine, conclusive evidence of the prophylactic value of tetanus toxoid was obtained during World War II. In addition the value of selectively prescribed tetanus antitoxin was reflected in the lowered mortality when the antitoxin was given in addition to toxoid at the time of injury; and the attenuating, if not preventive, effect of toxoid was indicated by the absence of deaths among cases given four or five injections before the onset of clinical tetanus.

The remarkable reduction of morbidity and mortality from tetanus during the later stages of World War I and during World War II focused attention on the sad statistics of other major wars. The comparative incidence of tetanus per 1,000 wounded has been tabulated as follows: Crimean War 2.0, American Civil War 2.07, Franco-Prussian War 3.5, Peninsular War (Wellington's campaign against Napoleon) 12.5.

**Incidence.**—Despite the worldwide distribution of the bacillus, comparatively few injured persons develop tetanus. In the U.S. the reported number of cases of tetanus decreased from 1,472 in 1920 and 560 in 1940 to less than 300 in the 1960s. Tetanus of the newborn has become relatively uncommon in the U.S. but persists in many other parts of the world. Tetanus in all age periods still appears with discouraging frequency in countries of high population density and low economic advantage. Postoperative tetanus, formerly attributable to contaminated catgut, is now rare. Adequate preventive measures have been credited with the reduced incidence of tetanus from wounds such as compound fractures, lacerations, and firecracker burns.

**TETENS, JOHANN NIKOLAUS** (1736–1807), German philosopher, mathematician, and economist, the most prominent representative of the Enlightenment (*q.v.*) philosophy in Germany, was born at Tetenbüll, South Schleswig, on Sept. 16, 1736. He was educated at the universities of Rostock and Copenhagen. He became professor of physics at Büttow University in 1763 and director of the *Pädagogium* (academy) there in 1765. In 1776 he was appointed professor of philosophy at Kiel University, where he later held the chair of mathematics. In 1777 he published his major work, *Philosophische Versuche über die menschliche Natur* ("Essays on Human Nature"; new ed. by W. Uebele, Berlin, 1913 et seq.). He gave up teaching and theoretical work in 1789 in order to enter public service, becoming assessor and then councillor of state and deputy in the Danish Ministry of Finance in Copenhagen, where he died on Aug. 15 (19?), 1807.

Tetens' *Philosophische Versuche* was the most important philosophical work written in Germany in the period immediately preceding Kant's *Critique*; it clearly shows the influence of the latter's *Dissertation* of 1770. In the preface to the *Philosophische Versuche* Tetens states, "metaphysical analysis . . . must be pre-

ceded by psychological analysis"; and further, "however far we proceed in metaphysical psychology, the authenticity of its propositions must always be tested by empirical knowledge." In this emphasis on the necessity of proceeding by way of construction in philosophy and on the importance of empirical foundations, Tetens approaches very close to the spirit of Kant, who valued his work highly and always kept a copy of the *Philosophische Versuche* on his writing table. Tetens was the only important German thinker to embrace, with some modifications, the empirical psychology in vogue in Great Britain and France during the 18th century; he calls the faculty of forming and combining ideas "understanding." In his threefold division of consciousness into feeling, will, and understanding he influenced Kant, to whose theory of knowledge these concepts are fundamental.

**TETRAGRAMMATON**, the four consonants, YHWH, of the name of the Hebrew God. See YAHWEH.

**TETRAHEDRITE**, a mineral consisting typically of copper sulfantimonide, but often of complex composition. It is an important ore of copper, in the pure form containing 57.5% of this metal; it is also largely worked as an ore of silver, of which it sometimes contains as much as 30%. The formula of tetrahedrite is  $\text{Cu}_3\text{SbS}_3$  but copper is usually isomorphously replaced by variable amounts of silver, iron, zinc, mercury, lead, or cobalt, and the antimony by arsenic or bismuth. Numerous special names have been applied to varieties differing in chemical composition; the arsenic compound,  $\text{Cu}_3\text{AsS}_3$ , is known as tennantite (after the English chemist Smithson Tennant). The old German name *Fahlerz* includes both tetrahedrite and tennantite.

Well-developed crystals are of frequent occurrence; they belong to the tetrahedral class of the cubic system and their tetrahedral form is a characteristic feature of the mineral. In the accompanying figure (A) shows a combination of a tetrahedron and a trigonal tristetrahedron, and (B) a tetrahedron with the rhombic dodecahedron.

CHARACTERISTIC CRYSTALS OF TETRAHEDRITE

The colour of the mineral is steel gray to iron black, and the lustre is metallic and brilliant. The streak is usually black; sometimes, however, it is dark cherry red, and very thin splinters of the mineral then transmit a small amount of blood-red light. The hardness is 4.5, and the specific gravity varies with the composition from 4.4 to 5.1. There is no cleavage and the fracture is conchoidal.

Tetrahedrite occurs in metalliferous veins, associated with chalcocopyrite and other sulfides. Fine groups of crystals, coated on their surface with brassy or brilliantly tarnished chalcocopyrite, were formerly found at Herodsfoot Mine, near Liskeard in Cornwall, Eng.

Tennantite occurred as small crystals of cubic or dodecahedral habit in many Cornish copper mines, especially in the neighbourhood of Redruth. It is also found as small, brilliant crystals very rich in faces in the white crystalline dolomite of the Binnenthal in the Valais, Switz., and under the name binnite was long considered as a distinct species. It occurs in the Harz Mountains of Germany, in Freiberg, Saxony, the silver mines of Mexico, Bolivia, and Peru, and in the United States in silver and copper mines in Arizona, Colorado, Montana, Nevada, and Utah.

(CL. F.; L. J. S.; X.)

**TETRAPODA**, the term for the backboneed animals with four limbs, the land vertebrates, including amphibians, reptiles, birds, and mammals. It is now primarily a term of convenience, but in some classifications it has taxonomic validity as a superclass collateral with the superclass Pisces (fishes) under the subphylum Vertebrata. See VERTEBRATE.

**TETRARCHY**, literally "rule of a quarter," is applied by the contemporary orator Demosthenes to the four governmental

divisions into which Thessaly was divided (342 B.C.) by Philip II of Macedonia. Under the Roman Empire the term was loosely used of any small principality in the eastern provinces, notably in Galatia, Syria, and Palestine. Herod the Great and his brother Phasael were made tetrarchs of Judaea by Mark Antony in 41 B.C. As king of Judaea, Herod had his brother Pheroras made tetrarch of Peraea by Augustus in 20 B.C. After Herod's death (4 B.C.) two of his sons were made tetrarchs: Antipas of Galilee and Peraea, Philip of Batanaea, Auranitis, and Trachonitis; his eldest son, Archelaus, who ruled Samaria, Judaea, and Idumaea, was given the higher title of ethnarch. In modern times the term tetrarchy is applied to the rule of four emperors under Diocletian and his colleagues between A.D. 293 and 305. (A. H. M. J.)

**TETRICUS** (GAIVS PIVS ESUVIVS TETRICVS), rival Roman emperor in Gaul A.D. 270–273, was a Gallic noble, related to Victoria and her son, the emperor Victorinus, under whom he was governor of Aquitania. On Victorinus' murder he was proclaimed emperor, apparently backed by the influence and money of Victoria. His very numerous coins mark the height of the 3rd-century inflation. It was apparently in his reign that Gaul experienced the worst incidence of the German invasions, and he was threatened by successive mutinies. When the emperor Aurelian appeared in Gaul with an army, Tetricus, after private treaty with his opponent, deserted to him in the course of the battle. Aurelian pardoned him, and appointed him governor of southern Italy.

(JN. R. M.)

**TETSCHEN**: see DECIN.

**TETUÁN** (TETOUAN), the chief town of Tetuán Province and Jabalah (Djéblé) region, Morocco, is 10 mi. (16 km.) from the sea, at the point where the Wadi (Oued) Martin crosses the limestone of Er Rif range at a height of 2,500–4,000 ft. (800–1,200 m.). Pop. (1960) 101,352. It is built on a rocky plateau, detached from the southern flank of the Jebel Dersa. The Roman Tamuda stood immediately above it. In the 14th century the Marinid sultans built a fortress there which became a corsair stronghold, provoking the Spanish expedition that led to its destruction. In the 16th century Tetuán was populated by Muslim refugees from Spain. Spanish troops first occupied it in 1860 and again in 1913; it then became the residence of the Spanish high commissioner and of the sultan's khalifa. The old town is still surrounded by ramparts on three sides, enclosing the suqs (market places) and the mellah (Jewish quarter). Apart from the well-developed handicraft trades, commercial activities include livestock, fruit and farm products, fish canning, and the manufacture of textiles, soap, matches, and building materials.

Tetuán Province comprises the western Rif, except the hinterland of Tangier. Cereals are grown on the fertile plains and hills where the principal rural markets (Alcázarquivir, Larache, and Arcila) are found. (G. L. M.)

**TETZEL** (TEZEL), **JOHANN** (c. 1465–1519), German Dominican preacher of indulgences and first public antagonist of Martin Luther, was born at Pirna in Meissen about 1465. After studying at Leipzig he entered the Dominican order, being appointed inquisitor for Poland (1509), and later for Saxony. Between 1503 and 1510 he was in constant demand as a preacher of indulgences. He became a preacher for the indulgence attached to the contributions to the construction of St. Peter's, Rome, in the diocese of Meissen (1516), and those of Magdeburg and Halberstadt (1517).

Tetzel's preaching at Jüterbog, near Wittenberg, in the spring of 1517 was the occasion for the publication of Luther's 95 theses at Wittenberg on Oct. 31, 1517, which provoked an uncompromising reply, published under Tetzel's name but really written by Konrad Wimpina. Tetzel grasped the explosive character of Luther's thought and saw that the main issue involved the very basis of the Catholic theory of the church, on whose authority he published 50 theses in May 1518. At the end of 1518 he withdrew to Leipzig priory, where he died on Aug. 11, 1519.

Tetzel was by no means a profound theologian and was far from orthodox in his teaching on indulgences for the dead. His view that a mere gift sufficed to secure this indulgence, together with the financial transactions surrounding the preaching of it, gave

rise to the grave abuses which helped to bring about the Reformation. In a sense the harm done by Tetzel was increased by his ability and appeal as a preacher. His style can be judged by specimen sermons he issued for the parochial clergy. For portrait, see article REFORMATION.

See N. Paulus, *Johann Tetzel der Ablassprediger* (1899). (I. Hr.)

**TEUTOBURG FOREST, BATTLE OF THE.** In the late summer of A.D. 9 three legions with auxiliary troops under the Roman commander P. Quintilius Varus were ambushed beyond the Rhine and destroyed by Arminius (*q.v.*), a chief of the Cherusci, allied with certain other German tribes. The circumstances of this battle, including its topography and even its precise date, have been the subject of a vast literature, since it has been generally believed that but for Varus' disaster Germany between the Rhine and the Elbe would have been romanized.

Tacitus (*Annals*, i, 60) indicated that the *Teutoburgiensis saltus* was near the country between the Ems and Lippe rivers; the modern name Teutoburger Wald for the range of hills south-east of Bielefeld was a 16th-century guess at his meaning. The identification is by no means certain, but it cannot be far wrong. Varus was moving from his summer camp just west of the Weser to a fort named Aliso on the Lippe (variously identified at points as far apart as Haltern and Paderborn) but had been deflected into difficult country to put down a supposed rising of which Arminius had deliberately given him news. Although Cassius Dio (3rd century A.D.) speaks of hills surrounding the army's route, Velleius Paterculus (a contemporary) and Tacitus emphasize the marshy terrain. If *saltus* meant "forest" rather than "mountain defile," the site might be west or northwest of the Wald, but this does not greatly alter the distance from the Roman bases on the Rhine.

As to the claims of Arminius to be *liberator Germaniae* (Tacitus, *Annals*, ii, 88), it must certainly be emphasized that in his day there was no united Germany and that Roman influence among the discordant tribes beyond the Rhine continued powerful for a long time to come. But in recent times it has also been denied that Augustus ever had any intention of annexing Germany east of the Rhine. Contemporary testimony (*e.g.*, Augustus' *Res Gestae*, 26, "... I pacified Germany . . . up to the mouth of the Elbe"; Velleius, ii, 97) is equivocal; there is no adequate archaeological evidence of occupation; and literary authorities say little or nothing about roadmaking, the construction of permanent camps and settlements, and the normal accompaniments of Roman rule. Yet the occupation was at most limited to 20 years, and aerial photography may still have something to reveal. The silence of Velleius, given the inexpert and prejudiced character of his military history, is not surprising, and Cassius Dio's full narrative is missing for the period 6 B.C. to A.D. 4. Accounts of Varus' activities in Germany up to A.D. 9 are certainly rhetorical, but all are agreed that he was imposing taxation and doing the judicial work associated with a Roman governor. If the period between the death of Drusus (9 B.C.; see DRUSUS, NERO CLAUDIUS) and the organization of a regular tribute-paying province seems long, the history of Moesia (*q.v.*) in the same period provides some parallel. It still seems likely that the loss of these three legions at a time of manpower shortage brought a drastic modification of Roman plans.

(G. E. F. C.)

**TEUTONIC ORDER, KNIGHTS OF THE** (German DEUTSCHER ORDEN or DEUTSCHER RITTERORDEN, that is, German Order of Knights of St. Mary the Virgin), a religious body which played a major role in Eastern Europe in the later Middle Ages.

**Origin.**—In 1189, when crusading forces were besieging Acre in Palestine (see CRUSADES), some German merchants from Bremen and Lübeck formed a fraternity to nurse the sick there. After the capture of Acre (1191) this fraternity took over a hospital in the town and began to describe itself as the Hospital of St. Mary of the German House in Jerusalem. Pope Clement III

approved it, and it adopted a rule like that of the original Hospital of St. John of Jerusalem. The death of the Hohenstaufen emperor Henry VI in 1197, when he was planning a great expedition to Palestine, caused an important change: a number of German crusaders who had arrived in Palestine decided to return home; to fill the gap the German princes and bishops, together with King Amalric II of Jerusalem, in 1198 militarized the fraternity, making it a religious Order of Knights.

The new Order was put under a monastic and military rule like that of the Templars (*q.v.*). It received privileges from Popes Celestine III and Innocent III and extensive grants of land, not only in the Kingdom of Jerusalem but also in Germany and in the Italian possessions of the Hohenstaufen German kings. It had a stronghold in Acre, but Montfort, in the hinterland northeast of Acre, became its main castle and was long the residence of its high master (*Hochmeister*, sometimes translated as grand master).

**Hermann von Salza.**—The Frankish states in Palestine and Syria, under pressure from the Muslims and torn by dissensions among their own rulers, offered only limited possibilities of successful establishment to the German nobles who joined the Order. The man who saw that clearly and found the solution to the problem was Hermann von Salza. Coming from the lower nobility of Thuringia, Hermann by sheer ability had made his way to the office of high master of the Order in 1210. He saw that the various motives behind the crusading movement were not strong enough to enlarge the Frankish outpost in the Near East; but meanwhile the rate of increase of Western Europe's population was still sufficient for an expansion of Christendom into Eastern Europe. Hermann therefore committed the Order to the German *Drang nach Osten*, or "Drive to the East" (see further GERMANY: History).

The Order's first European enterprise started in Hungary in 1211, when King Andrew II invited a group of the Knights to protect his Transylvanian borderland against the Kumans (*q.v.*) by colonizing it and by converting its people to Christianity. The Order was then granted extensive rights of autonomy; but the Knights asked more in this direction than their hosts were prepared to grant, and in 1225 the Order was expelled from Hungary. By that time, however, a new opportunity was opening: a Polish duke, Conrad of Mazovia, with lands on the lower reaches of the Vistula River, needed help against the pagan Prussians (see PRUSSIA).

Earlier in the 13th century the Cistercian monk Christian of Oliva, who was probably of Polish origin, had begun to preach Christianity to the Prussians. Pope Innocent III consecrated him bishop of Prussia in 1215; but soon afterward a pagan reaction forced Bishop Christian to seek political and military backing from Conrad of Mazovia. Conrad granted castles and lands around Chelmino (Ger. Kulm), on the right bank of the Vistula, to the bishop; but the latter was unsuccessful in organizing crusades from this Kulmerland, which the Prussians overran. Conrad then invited the Teutonic Order to take control (1225 or 1226).

Hermann proceeded very carefully, in order to avoid a repetition of what the Order had experienced in Transylvania. He already enjoyed the confidence of the Hohenstaufen emperor Frederick II, whom he had served as a diplomat. So, when Conrad made his offer, Hermann in 1226 obtained from Frederick the so-called Golden Bull of Rimini as a legal basis for the settlement. By this charter, Frederick confirmed to Hermann and to the Order, not only the lands to be granted by Conrad, but also those which the Knights were to conquer from the Prussians. Whereas previously the Papacy had enunciated a principle of liberty for the converted Balts and had represented political and military intervention as a transitory necessity, the text of Frederick's charter emphasized that the subjection of the pagan peoples was no less important than the conversion of them to Christianity; and Frederick endowed the high master of the Order with the same administrative and jurisdictional rights as were exercised by the princes of the Empire. Identity of territorial functions, however, did not make the high masters princes of the Empire themselves; princes were immediate vassals of the emperor (see FEUDALISM; PRINCE), and the Golden Bull of Rimini made no mention

of any feudal link between high master and emperor. Obviously Hermann did not intend to break the custom, developed since Pope Gregory VII's time, that no ecclesiastic, except bishops and those Benedictine abbots who had been "members" or princes of the Empire for centuries, should become the vassal of a secular ruler.

Hermann's intention of keeping his relations with the Papacy intact is illustrated by his obtaining a new privilege from Pope Gregory IX in 1234, which can be regarded as the second foundation charter of the Order's Prussian state. When Conrad of Mazovia had formally granted the Kulmerland and had effectively ceded a base on the left bank of the Vistula to the Order (1230) and when Bishop Christian had fallen into the hands of the Prussians (1233), the Papacy was ready to accept the Order's present and future conquests as the property of the Holy See and to grant them back to the Order in perpetual tenure.

In 1230 Hermann von Salza sent Hermann Balk to be land master (*Landmeister* or provincial head) of the Order's new territory. A series of well-prepared campaigns began with the invasion of the Kulmerland in 1231; and in 1233 a general crusade for the conquest of Prussia was launched. The Knights themselves formed only a skeleton force, directing operations and consolidating their results. The main bulk of the armies was to consist of crusading laymen, volunteers for a definite term of service. This supply of volunteers, however, was not left to chance. Hermann von Salza, who moreover had increased the Order's possessions around Halle in central Germany, made contact with the lands under the archbishop of Magdeburg and concluded an alliance with the House of Wettin (*q.v.*), which was already powerful on the middle Elbe River. Also he got help from Silesia and from Bohemia. Finally, transport problems were largely solved through Hermann von Salza's understanding with Lübeck, whose citizens were pioneers of long-distance shipping in the Baltic.

Hermann von Salza died at Salerno, in Italy, on March 20, 1239.

**The Knights of the Sword.**—In 1237, less than two years before Hermann von Salza's death, the Order of the Brothers of the Sword (*Schwertbrüderorden*), also known as the Knights of the Sword or the Livonian Order, which had been founded in 1202 to help the bishops of Riga to christianize the lands at the eastern end of the Baltic, was made a branch of the Teutonic Order, its head becoming land master of Livonia (*q.v.*). The Teutonic Order, however, never established such effective control over these northern provinces as it did over Prussia: its authority there was sharply contested by various bishoprics (Riga became an archbishopric in 1245); northern Estonia was under Danish suzerainty till 1346; an attack by the Knights on the neighbouring Russian state of Novgorod led to their defeat by Alexander (*q.v.*) Nevski on Lake Peipus in 1242; and Courland (*q.v.*), the southern part of the Livonian land master's province, was connected with Prussia only by a very narrow strip of coastland, since Samogitia, the hinterland, remained in the possession of hostile Lithuania (*q.v.*) except for the brief period 1398–1411. For further details on the Knights of the Sword, see *ESTONIA: History*; *LATVIA: History*.

**The Colonization of Prussia.**—With the help of the volunteer crusaders, the Teutonic Order pushed its Prussian conquests farther and farther toward the lower Neman (Niemen, Nemunas). By 1260 it was already in possession of Samland, the country north of the Pregel estuary. Castles were built to form a network of military and administrative centres (there were 23 of them by the end of the 13th century), the more important ones being the seats of commanders of districts, each with his convent of knights-brethren. The architecture was of a uniform type: a bulky square of brick walls round a courtyard, with a defensive system of deep ditches.

Apart from the members of the Order, who were of course celibate, lay members of the knightly class who had come as volunteer crusaders might receive lands for themselves and their families to hold as fiefs from the Order, in return for military service. Up to the 1260s these grants of land might be very large, and during this period only about 100 families were thus settled.

The Order also proceeded to found German towns: marketplaces

with a German population were established—probably in localities where the indigenous Prussians had traded with their western neighbours before the Order's arrival. A charter known as the *Kulmer Hundfeste* (1233) granted liberty of river traffic and local jurisdiction to Kulm and to Thorn (Torun); and towns which grew up later, including Königsberg (originally a military stronghold; see *KALININGRAD*), received privileges on the same model. Before the end of the 13th century, moreover, the Order was controlling the production of grain in its territory and taking charge of the export of grain overseas.

At first the settlement of German peasants was on a comparatively small scale. In 1261, however, a great insurrection of the subject Prussians broke out, and for 12 years the Order's survival in Prussia was threatened. A further decade of violent fighting restored the Order's supremacy. A new land policy was adopted in the 1280s: many of the larger holdings of the German vassals were reduced in order to provide land for more settlers, whose number subsequently rose to about 500 families, and a strong influx of German peasants was organized. Cultivation spread gradually from the lower Vistula and the Baltic coast to the southern and southeastern borderland, which had previously been left wild. Immigration continued till 1410, notwithstanding the decline of Europe's population and economic stagnation in the second half of the 14th century. (See further *PRUSSIA*.)

Montfort, behind Acre, fell to the Muslims in 1271, and Acre itself fell in 1291. The high master Konrad von Feuchtwangen then moved his seat to Venice; but in 1309, when Philip IV of France was destroying the Order of the Templars (*q.v.*), the Teutonic high master Siegfried von Feuchtwangen took the precaution of transferring his residence to Marienburg (Pol. Malbork), on the easternmost bank of the Vistula delta. Thenceforward successive high masters were themselves land masters of Prussia, while the Order's possessions in Germany were under a *Deutschmeister* or "German master" and Livonia remained under a land master of its own. In Marienburg the high master held court in a great brick building in the North German type of the Gothic style; his permanent council, comprising the other grand officers of the Order, became something like the ministry of a modern state.

**Polish and Lithuanian Relations.**—From the end of the 13th century the Order's foreign policy was determined by the need to reduce the isolation of Prussia. When the succession to Pomerelia, that is, to the easternmost part of Pomorze (*q.v.*), was in dispute between Poland, Brandenburg, and the Teutonic Order, the Knights took Danzig (Gdansk) in 1308 and obtained Brandenburg's assent to their annexing most of the rest of Pomerelia in 1309. They thus won a territorial link with the lands on the Oder River, feudally dependent on the German kingdom; but in so doing they cut Poland off from access to the Baltic. In the east, however, the Lithuanians still resisted the Order's attempts to widen the corridor between Prussia and Courland.

Poland and Lithuania were inevitably antagonized by the Order's expansion. The Lithuanian Gediminas (*q.v.*) and Wladyslaw I (*q.v.*) of Poland fought against it; and though Wladyslaw I's successor Casimir III (*q.v.*) made the Peace of Kalisz (1343) with the Order, the anti-German reaction continued to grow in strength among the Eastern European peoples. Moreover, the death of the Holy Roman emperor Charles IV (1378) was followed by the disintegration of the great block of territory which his dynasty, the House of Luxembourg, had built up on the Elbe and Oder Rivers; and this meant that the prospect of efficient support for the Order from the Empire was seriously reduced. The Lithuanian prince Jogaila (Jagiello) promised to cede Samogitia to the Order in 1382; but his marriage to the Polish queen Jadwiga, in 1386, radically changed the situation. Becoming king of Poland, as Wladyslaw II (*q.v.*), and accepting Christianity for himself and for his people, he could threaten the Order with a powerful coalition along its southern and eastern borders at the same time as he deprived it of all pretext for a crusade.

Vytautas (*q.v.*) of Lithuania, temporarily estranged from Poland, ceded Samogitia to the Order in 1398; but in 1401 Wladyslaw II and Vytautas were reconciled. Rebellion against the

Order in Samogitia began in 1408, the high master Ulrich von Jungingen attacked Poland in 1409, and the Poles and Lithuanians defeated the Knights in the Battle of Grunwald (*q.v.*) in 1410, at which Ulrich was killed. Heinrich Reuss von Plauen successfully defended the Marienburg, but had to renounce Samogitia to Lithuania and the Dobrzyn Land (southeast of the Kulmerland) to Poland at the First Peace of Torun in 1411, which also imposed a heavy ransom for captives.

A general collapse of the Order's moral and political authority ensued. Wartime devastation, coupled with a recession in the Baltic trade, ruined the economy, and Poland did not relax pressure. Heinrich Reuss von Plauen, elected high master in 1411, was deposed in 1413 by a faction hoping vainly to conciliate the Poles. Moreover, the secular nobles in Prussia, regarding the Order's political status as an anachronism, saw no treason in cooperating with Poland. In 1440 the nobles and the towns formed the Prussian League to assert themselves against the Order; and in 1454 Casimir IV of Poland responded to their appeal for military help. After a long war, during which the high master Ludwig von Erlichshausen had to move his residence to Königsberg (1457), the Second Peace of Torun (1466) was concluded: the Order ceded Pomerelia and the left and right banks of the Vistula, together with the bishopric of Warmia (Ermland), to Poland. The rest of Prussia was left to the high master as a subject of the Polish crown.

**The End of the Knights.**—The Teutonic Order's rule in Prussia came to an end in 1525, when the high master Albert (*q.v.*), under Lutheran influence, dissolved the Order there and accepted its territory as a secular duchy for himself under Polish suzerainty (see also HOHENZOLLERN; PRUSSIA). The land master of Livonia held his province for his Order till 1558; then most of its territory was partitioned between Russia, Sweden, and Poland-Lithuania, and in 1561 the land master Gotthard Kettler became secular duke of Courland, as a vassal of the Polish king. Meanwhile, in 1530, the emperor Charles V had made the still Catholic *Deutschmeister* a prince of the Holy Roman Empire; the latter's successors, with their seat at Mergentheim on the Tauber River, controlled the Order's lands in central and southern Germany till 1809, when Napoleon, at war against Austria, declared the Order to be dissolved and distributed its lands among other principalities. The Austrians reestablished the Order in Vienna, as an ecclesiastical institution, in 1834.

**TEUTONIC PEOPLES:** see GERMANIC PEOPLES.

**TEVFIK PASHA, AHMED** (AHMET TEVFIK PASA) (1845–1936), the last Ottoman Turkish grand vizier, was born in Istanbul on Feb. 11, 1845. His father, Ferik Ismail Hakki Pasha, was the commander of the Danube region. Ahmed Tevfik was of Crimean descent. He graduated from the military cadet school as a lieutenant in 1862. Four years later he resigned his commission and joined the foreign service to become in 1871 second secretary to the embassy in Florence. He served in various embassies and was appointed chargé d'affaires to St. Petersburg in 1877. On the declaration of war with Russia he returned to Istanbul and was appointed political adviser to Abdul-Kerim Pasha, commander of the region with headquarters at Sumnu in Bulgaria.

In 1895, after 10 years as ambassador in Berlin, Tevfik Pasha returned to Istanbul to become foreign minister, a post he held for 14 years. After the Young Turk Revolution of 1909 he was made grand vizier. When Abdul-Hamid II was forced to abdicate, Mehmed V (1909–18) kept him as grand vizier, but he resigned and became ambassador in London. There he remained until World War I. During the war he served as member of the Senate. He became grand vizier again after the armistice (1918), but fol-

lowing the occupation by the Allies he resigned and again became a member of the Senate. In 1919 he was head of the first delegation to the Paris peace conference, but he was ill received by Clemenceau and had to return. He went there again in May 1920 but refused to sign the Sèvres peace treaty because he considered it incompatible with Turkish sovereignty. In 1920 he became grand vizier for the third time and headed the Turkish delegation to the London peace conference in February 1921. There he openly declared his support for the Turkish representatives from Ankara. When the Sublime Porte government came to an end in November 1922, he was still grand vizier. He died in Nisantasi, Istanbul, in 1936.

(M. P. P.)

**TEVIOT**, a river of Scotland, flowing near the southern border. Teviotdale comprises a large part of Roxburgh. The headstreams rise at about 1,500 ft. (460 m.) in the watershed between Teviotdale and Eskdale around Wisp Hill (1,950 ft. [594 m.]) on the Dumfries boundary. The river flows northeast for about 37 mi. (60 km.), past the town of Hawick, and joins the Tweed (*q.v.*) at Kelso. It is joined on the right by the Slitrig, the Rule, and the Jed, on the left by the Borthwick and the Ale. All of them are trout streams, and the Teviot also has some salmon fishing. The Teviot is a fairly rapid and shallow stream winding between terraces (haughs) across a flat-floored valley with steep bluffs, at first narrow in hill country, then about a half mile wide in a broader dale, then widening out among the rolling ground-moraine hummocks of the main lower basin of the Tweed. (A. T. A. L.)

**TEWFIK PASHA, MOHAMMED** (MUHAMMAD TAWFIQ PASHA) (1852–1892), khedive of Egypt, eldest son of the khedive Ismail, was born in Cairo on April 30, 1852. He had a difficult upbringing; his father, mistaking his mildness for stupidity, neglected his education. Nevertheless, he was for a few weeks president of the Council of Ministers during the crisis which precipitated Ismail's deposition on June 26, 1879. Summoned by Sultan Abdul-Hamid II to succeed his father, he adopted a cooperative, if passive, attitude toward Anglo-French control of Egyptian state finances. Nationalist opposition to foreign influence increased from September 1881 when he was faced by a military mutiny. In February 1882 he was forced to accept a Nationalist ministry with Arabi Pasha (*q.v.*) as minister of war. Tewfik Pasha's position in the capital having become intolerable, he retired to Alexandria where he stayed during the disorders and British naval bombardment in July. On Sept. 25, after the collapse of the Nationalist revolt, he returned to Cairo under the protection of the British army. Relying solely on the advice of Sir Evelyn Baring (later earl of Cromer), the British representative he acquiesced in the British occupation and in 1884 reluctantly agreed to the British request for Egyptian withdrawal from the Sudan. Tewfik Pasha took a special interest in irrigation, education, and justice. He showed little desire to keep up the unapproachable state of an Oriental ruler, and in many ways his manners were less Oriental than European. He was a strong advocate of monogamy. He died at Hulwan on Jan. 7, 1892, and was succeeded by his son, Abbas Hilmi Pasha.

See Earl of Cromer, *Modern Egypt*, 2 vol., 2nd ed. (1911). (R. L. HL.)

**TEWKESBURY**, an ancient market town and municipal borough in the Cirencester and Tewkesbury parliamentary division of Gloucestershire, Eng., stands near the confluence of the River Severn (which forms the parish boundary for some miles) and the Warwickshire Avon, 11 mi. (18 km.) N of Gloucester and 9 mi. (14 km.) NW of Cheltenham. Over the Avon is the medieval King John's Bridge. Pop. (1961) 5,822.

The town's most striking feature is the abbey church of St. Mary, founded by Robert Fitz Hamon and consecrated in 1123. It occupies the site of a Saxon hermitage, built by the monk Theoc (Theuk), from whom the place is said to have derived its name, and that of a small Benedictine abbey (founded in 715). The tower and nave were finished in 1150, and after the church had been largely destroyed by fire in 1178 important rebuilding took place. In the 15th century the Despenser family was responsible for considerable additions including the clerestory of the choir and several of the chantry chapels. The abbey was relinquished

in 1539/40 but the choir, transepts, and central tower were purchased by the people of Tewkesbury for £453, while practically all the conventual building was destroyed. The impressive square Norman tower (148 ft. [45 m.] from ground to pinnacles and 46 ft. [14 m.] wide) affords extensive views over the low-lying countryside. The nave has seven Norman pillars on each side, more than 30 ft. (9 m.) high and 6 ft. (2 m.) in diameter. The 14th-century groined vaulting of the roof has a fine series of carved bosses; the west arch and window can be seen to advantage from outside. The window dates from 1686, the earlier one having been destroyed by a storm in 1661. There are interesting early tombs, particularly those of the Despensers. Restoration work was started in 1875 by Sir George Gilbert Scott.

The earls of Gloucester made Tewkesbury a free borough in the 12th century; the charter of liberties granted by William III in 1698 still remains in force.

There are many fine old houses ranging from half-timbered Tudor and Jacobean, with overhanging upper stories, to attractive red-brick buildings of the Queen Anne and Georgian periods. A quaint watermill is near the abbey and notable and picturesque inns include the Hop Pole, mentioned in *Pickwick Papers*, and the Bell, featured in the novel, *John Halifax, Gentleman*, by Mrs. Craik (Dinah Maria Mulock). The Black Bear, dating from 1308, is perhaps the oldest inn in Gloucestershire. The Tudor House Hotel in the High Street was formerly the old Academy founded in 1712 by the Rev. Samuel Jones of Pennsylvania. At the Cross is held the town's annual October fair, the site of the ancient Barton Market. Tewkesbury, reputedly famous for mustard in Shakespeare's day, is a centre for boating and angling, particularly on the slow-flowing Avon; its main industries are flour milling, engineering, and boat building. (B. C. F.)

**Battle of Tewkesbury.**—In this battle (May 4, 1471) of the Wars of the Roses (*q.v.*) Edward IV finally defeated his Lancastrian opponents. Queen Margaret, wife of the imprisoned Henry VI, had landed at Weymouth from France with her son, Prince Edward, on April 14, the day of the Yorkist victory at Barnet. She was subsequently joined by Edmund Beaufort, duke of Somerset, his younger brother John, and John Courtenay, earl of Devon, who persuaded her that Lancastrian strength in the west was still unbroken; accordingly, after a halt at Exeter, the army struck inland toward the Welsh border. Edward IV, having reorganized his troops, marched from Windsor on April 19 to intercept the Lancastrians. On May 2 the armies made contact at Chipping Sodbury, but the Lancastrians slipped away toward Gloucester, where they hoped to cross the Severn. Refused admission to the town, they hurried north, and on the afternoon of May 3 entrenched themselves just south of Tewkesbury. The Yorkists, coming from Cheltenham, camped just a little farther south. Battle was joined the next morning, each side being about 3,000 strong. The duke of Somerset commanded the Lancastrian right, Prince Edward the centre, and the earl of Devon the left. Richard, duke of Gloucester, led the Yorkist left, King Edward the centre, and Lord Hastings the right. The Lancastrians had a useful defensive position, but Somerset sought to turn the Yorkist left by a surprise attack through the wooded ground on his own flank. This attempt miscarried, the Yorkists broke the main Lancastrian position, and the Lancastrian centre collapsed. Some, fleeing toward the river, were slain in Bloody Meadow, others by the abbey mill. About 1,000 perished, including Prince Edward, Devon, and Somerset's brother John. Somerset, dragged from the abbey, was executed on May 6; Queen Margaret was taken from hiding on May 7. The murder of Henry VI in the Tower completed the Lancastrian ruin.

See W. Bazeley, "The Battle of Tewkesbury," *Transactions of the Bristol and Gloucestershire Archaeological Society*, vol. xxvi (1903); A. H. Burne, *The Battlefields of England*, 2nd ed. (1951). (Gx. T.; X.)

**TEXARKANA**, an urban community on the boundary line of Texas and Arkansas, U.S., 165 mi. NE of Dallas. First settled in 1874, Texarkana, Tex. (Bowie County), was incorporated in 1875; Texarkana, Ark. (seat of Miller County), in 1881. The two cities have separate municipal governments but are integrated eco-

nomically. Texarkana is a retail and wholesale distribution point for a large area. A railroad and bus centre, the community has many manufacturing plants. Ordnance plants of the U.S. Army are located nearby. Pop. (1960) community, 50,006 (Texarkana, Tex., 30,218; Texarkana, Ark., 19,788); standard metropolitan statistical area (Bowie County, Tex., and Miller County, Ark.), 91,657. For comparative population figures see table in ARKANSAS: *Population* and in TEXAS: *Population*. (N. McG.)

**TEXAS**, popularly known as the "Lone Star State" for the single star in its flag, a west south-central state of the United States, won independence from Mexico in 1836, was a republic until 1845, and was then annexed by the U.S., becoming the 28th state. Bounded on the southwest by Mexico, on the west (but north of its Trans-Pecos region) by New Mexico, on the north by Oklahoma, on the northeast by Arkansas, on the east by Louisiana, and on the southeast by the Gulf of Mexico, its total boundary is 2,845.3 mi. (4,580 km.), including major bends of rivers and seacoast. Its area is 267,338 sq.mi. (692,406 sq.km.) (262,969 sq.mi. [681,090 sq.km.] of land and 4,369 sq.mi. [11,316 sq.km.] of water surface), and in size it ranks second only to Alaska. The state flower is the bluebonnet, the bird the mockingbird, the tree the pecan, the song "Texas, Our Texas." The state flag consists of a blue perpendicular stripe (next to the staff) on which is placed a single white star; and two horizontal stripes, the upper white, the lower red. The capital is Austin (*q.v.*).

Obscured by a mist of myths conceived by others and by fictions maintained by its own, Texas has been extravagantly praised and deplored from its beginning. An early example of censure was a 16-page pamphlet written in 1845 by Edward Everett Hale: *How to Conquer Texas, Before Texas Conquers Us*. The tone of the censure had not changed much a century later. Never less than sixth of the U.S. states in population in every federal census from 1900 to 1960, second largest in area, and first in its capacity for illusion, Texas is the only state to have been an independent nation (1836-45) before joining the Union. More than any other member of the former Confederate States of America (1861-65), Texas escaped the economic and social penalties of being a unit of the American South after 1900 but beginning notably in the 1940s. Petroleum and later petrochemicals were its stimulants.

So great are its area and diversity, which are causes of problems peculiar to it, that Texas is easier to comprehend as a region than as a state. Indeed, it is unique in having the right to divide itself into more states, an event even less likely of realization than the transformation of Texans into a taciturn people. The joint resolution on the state's annexation to the U.S. says: "New States of convenient size, not exceeding four in number, in addition to the said State of Texas . . . may hereafter, by the consent of said State, be formed . . ." Any definition of the state's character is imperfect, a result of its vast area and diversity. The culture of the Rio Grande Valley is foreign to that of the Great Plains area, hundreds of miles to the north. The concerns of the El Paso region are seldom those of the Texas that touches Louisiana, nearly 800 mi. (1,290 km.) to the east. Dalhart, in the Texas Panhandle, is nearer to the capitals of New Mexico, Kansas, Colorado, Oklahoma, and Nebraska than to the capital of Texas. The state's area is as much an obstacle as an advantage.

Texas is almost exactly midway between the Atlantic and Pacific oceans. Its 624-mi. (1,000-km.) seacoast (tidewater) is the third longest of the conterminous states. It has a border touching a foreign nation whose civilization, language, and dominant religion differ from its own longer than all the rest of the states together. It is a land of extremes, and of such almost inconceivable variety that there is no way to compare it with any other state, not even with any other equal land area in the nation. Its mineral wealth is its fortune: since the 1930s it has been first among the states in the value of its mineral production, mainly oil and natural gas.

The historian Walter Prescott Webb has shown that by accident "Texas stands in the physical path of a special destiny." The accident is a cultural triangle in which three natural environments, three molds of separate cultures, meet and oppose each other in Texas: the woodlands, the plains, and the desert. There is also a fourth, the sea.

Texas is the only state to retain ownership of its public lands, a circumstance of large importance in financing education. The republic of Texas claimed a public domain of more than 225,000,000 ac. (91,057,500 ha.). By the Compromise of 1850, 72,892,000 ac. (29,499,400 ha.) of this land were transferred to the U.S. for \$10,000,000 and, in 1855, an additional \$2,750,000. The transferred land eventually formed parts of the states of New Mexico, Kansas, Colorado, and Wyoming. Nearly 52,000,000 ac. (21,044,400 ha.), or roughly 30% of the state's total area, were given to benefit public education, later endowed by land sales, rents, mineral leases, and royalties.

More important are the distinctive contributions of Texas to Western civilization: the union of the common and the civil law that produced the doctrines of community property and homestead exemption, the abolition of special pleading, and the blending of law and equity in a single court. These innovations, growing out of the Texas revolution, have spread not only throughout the U.S. but to some extent throughout the English-speaking world.

### PHYSICAL GEOGRAPHY

**Physical Features.**—Texas (lying between longitude 93°31' and 106°38' W and latitude 25°50' and 36°30' N) tilts to the southeast, as if propped up against the western mountains. Thus the streams flow from the northwest to the southeast, almost parallel with each other. Eight of them (Sabine [*q.v.*], Neches, Trinity, Brazos, Colorado [*q.v.*], Guadalupe-San Antonio, Nueces, and Rio Grande [*q.v.*]), empty into the Gulf of Mexico. The Rio Grande, longest of the rivers, forms the southwestern boundary of Texas. The Red River (*q.v.*), second longest and the only one of importance not bearing a Spanish name, is part of the northern boundary, and the Sabine is part of the eastern boundary.

The Balcones fault is a natural partition having an extraordinary effect on the state's history, culture, and economy. Cutting Texas in two in an irregular line, the fault extends east from the Rio Grande, near Del Rio, to San Antonio, northeast to Austin, and, after bulging to the west, northeast to the Red River east of Wichita Falls. East of the fault lies roughly 40% of the state's area, all of its most populous cities except El Paso, far to the west, and most of its wealth and rainfall. The region east of the line is humid and buoyant; that west of it is dry and comparatively hard up except where it has been sweetened by irrigation or the discovery of oil.

Texas is divided by the four North American physiographic regions that extend into it: the Gulf coastal plain, entering from the east; the central lowlands, from the north; the Great Plains, from the northwest; and the eastern ranges of the Rocky Mountains, which cross the Texas Trans-Pecos region (the western part of the state between the Rio Grande and the southern boundary of New Mexico), also from the northwest.

**Gulf Coastal Plain.**—The Gulf coastal plain covers the favoured 40% of Texas east of the Balcones fault. The region, rising from sea level to an elevation of 800 ft. (245 m.), is divided into five fairly distinct areas. The coastal prairies, extending 75 to 100 mi. (120–160 km.) inland between Corpus Christi and Port Arthur, comprise one of the richest agricultural and mineral areas of the state, yet also the most urban and industrial. This is the economic heartland of Texas. Entering the state from the east and extending 100 mi. westward are the southern yellow pine forests. West of the pine belt is one of secondary forest growth, popularly known as the post-oak belt. Adjacent to the post-oak belt are the fertile blackland prairies, which extend in a long, narrow V-shape from the Red River on the north to the fifth area, the Rio Grande Plain, on the southwest. The last, south and southwest of San Antonio, is popularly known as the brush country, or Chaparral, but it also includes in southernmost Texas the lower Rio Grande Valley. The valley is a small but important area, with a year-round growing season, that is rich in irrigated citrus and winter vegetable production.

**Central Lowlands.**—Flanked by the coastal plain on the east and by the Great Plains on the west and south are the central lowlands, reaching into Texas from the north in a belt nearly 200 mi. wide. Sloping upward from an elevation of 800 ft. on its eastern edge

to 2,500 ft. at the cap rock escarpment separating the central lowlands from the Great Plains province on the west, the region is divided into three areas. On the east, extending north and south from the Red River into central Texas, is the Grand Prairie, a sharply rolling country. On the eastern and western edges of the Grand Prairie are minor forest areas known as the Cross Timbers; the larger West Cross Timbers is a hilly area spotted with post-oak woodlands and prairies. West of it are the rolling prairies, largely covered with mesquite, which extend to the Great Plains region on the west.

**Great Plains.**—The Great Plains (*q.v.*) region in Texas, a vast L-shaped province west and south of the central lowlands and west of the Gulf coastal plain, extends to the eastern slopes of the Rocky Mountains. The region rises abruptly from an elevation of 2,500 ft. (760 m.) at the well-defined cap rock escarpment on the east and very gradually slopes upward to an elevation of 4,600 ft. (1,400 m.) at the New Mexico boundary. The generally flat area is broken on the north by several canyons, notably the Palo Duro Canyon of the Red River. The region may be divided into three areas (but two of them, the Edwards Plateau and the central Texas Basin, are often classed as parts of the central lowlands, with which in some ways they are more in character). The larger area to the north is the Staked Plains, or Llano Estacado (*q.v.*), itself divided into the North and South plains. The Edwards Plateau, forming more than half of the bottom of the L, extends eastward to the Balcones fault. A rugged limestone tableland comprising nearly an eighth of the state's area, it is almost as flat as the Staked Plains. Between the plateau on the south and the central lowlands on the north is the central Texas Basin, itself divided into the Texas hill country, a resort and vacation area, and the Burnet-Llano Basin on the north. The hilly central Texas Basin is in an intermediate stage of erosion between the youth of the Edwards Plateau and the old age of the central lowlands. Many exceptions must be made, however, when the Edwards Plateau and the central Texas Basin are included in the Great Plains region. As the eastern edges of both are on the Balcones fault (elevation 800 ft.), they are exceptions to the Great Plains' elevation range of 2,500 to 4,600 ft.

**Rocky Mountains.**—The Rocky Mountain region that crosses Trans-Pecos Texas from northwest to southeast is the most barren but in many ways the most interesting of the state's four physiographic regions. It includes desert lands, the highest mountains in Texas, and the strange beauties and contrasts of the Big Bend National Park. Its lowest elevation is 2,000 ft. (610 m.) at the eastern edge of the Stockton Plateau and elsewhere; its highest elevation is Guadalupe Peak, 8,751 ft. (2,667 m.). Sparsely populated except for El Paso in the westernmost tip of Texas, the region is divided into five areas. They are, from east to west, the Stockton Plateau, a rolling plain that is a Trans-Pecos extension of the Edwards Plateau; the Big Bend National Park; the Davis Mountains, which reach an elevation of 8,382 ft. (2,550 m.) in Mt. Livermore; the Diablo Plateau, a high plateau that includes Guadalupe Peak; and the upper Rio Grande Valley at the western tip of Texas, chiefly a mountain and desert area except for a narrow, irrigated alluvial strip, 100 mi. long and important for its cotton production, along the Rio Grande.

**Popular Division.**—The people of Texas more commonly think of the state as being divided into seven geographic regions. Under other circumstances of history these regions might reasonably have become separate states. Each has distinctive physical features as well as to some extent an economy and culture of its own. In the mind's eye of most Texans these regions are virtually provinces whose names are proper nouns: (1) east Texas, spared the mildew of William Faulkner's Deep South by its oil; (2) the Gulf Coast, a golden littoral of energy and cities; (3) the Rio Grande Valley, the almost-tropics, with its chain of small cities that together are the fourth largest city in Texas; (4) the Border, indelibly Mexico and the valley's cast-off kin; (5) west Texas and the Trans-Pecos, the last the desert, the first the Old West of romantic fiction, side by side and sharing drought's poverty of purse and spirit; (6) the Panhandle, with nothing to rest the eye on not even a tree, except the surprise of cities rising from the Great

Plains; and finally (7) central Texas, the vast middle region, pragmatic and more stable than the others. Here in the centre the other six regions merge and lose their identities in what, in the small towns, is fancied to be the heart of Texas—rural civilization.

The extraordinary diversity of the state's climate, soil, vegetation, and animal life is caused in part by its location but to a larger extent by its enormous area, a fact so obvious as to be neglected when Texas is compared with any other state. This land area, a twelfth of the area of conterminous U.S., must be always held in mind to give proportion to superlatives of the state's physical geography and in some cases to understand that the superlatives are not so exceptional as they may at first seem. (Even more must the state's area be held in mind in evaluating its leading position in many categories of agricultural and mineral production, later subjects.) The land area of Texas is larger than that of France, the largest country in Europe; it is larger than the combined area of many states. To make statistical comparisons of Texas with other states is often unrealistic. For instance, the state does not produce more cotton than any other state because its growers are more efficient or its land more fertile or because it produces more cotton per acre (it does not) but because it has so many acres on which to grow cotton.

**Climate.**—Texas lies almost wholly in the belt of medium (mesothermal) temperatures, and the state has been variously divided into climatic regions (usually 12) of temperature and rainfall. On all aspects of the state's physical geography, however, climate is revealed the least by scientific or technical exposition. It may be that the excesses of Texas weather provided Texans' earliest impetus toward exaggeration—the gasconade and flamboyance that have become characteristic.

In late autumn, winter, and early spring, cold winds blow down across the top of Texas, pushing rapidly across most of the state, sometimes reaching as far as the lower Rio Grande Valley in southernmost Texas. Texans call the cold waves "northers," blue northers, wet northers, or dry northers. The chief characteristic of a norther that distinguishes it from what other people call a cold wave is the sudden, dramatic fall in temperature. Such a decline may amount to 20° or 30° F (11° to 17° C) in two or three hours, but temperatures fall below 32° F (0° C) only for short periods. Texas weather is often violent: July to September is the season of greatest hurricane activity, and tornadoes strike through a wide east-west band of the state. A study by the U.S. Weather Bureau in 1952 showed that Texas averaged 14 tornadoes a year between 1916 and 1950. In 1953, the most destructive year for tornadoes in the state's history, four twisters killed 142 people, injured 781, and damaged or destroyed more than \$40,000,000 worth of property.

All Texas is sometimes cold in the winter, and all of it is hot nearly every day in the summer. Mean annual temperatures range from 55° F (13° C) at the top of the Panhandle to 74° F (23° C) in the lower Rio Grande, the temperatures rising in roughly parallel, east-west belts. Rainfall averages more than 55 in. (1,397 mm.) annually in the small easternmost section of the state, decreasing gradually, in north-south belts, to the west until it is less than 10 in. (254 mm.) annually at El Paso. Snow averages 20 in. (508 mm.) annually in the northern Staked Plains and in some of the mountain areas, but otherwise snow is not a factor in Texas weather.

**Soil.**—Roughly 130 soil series, divided into more than 500 soil types have been identified in Texas. The state's surface has been divided into 14 land resource areas (broad areas of more or less uniform soil, topography, climate, and vegetation), but its soils may be grouped into six general classes. These are the heavy coastal clays, including the river bottoms extending into the interior of the state; the sandy and sandy clay soils of the east Texas timber belt; the limestone soils of the blackland prairies, Grand Prairie, Edwards Plateau, and parts of the Trans-Pecos area; the mottled red and gray loam soils of north central Texas; the sandy and sandy loam soils of the high plains; and the rough stony lands of the Trans-Pecos and large areas of southwest Texas.

**Vegetation.**—Natural life in North America has been more profoundly affected by fencing than by any other of man's de-

vices, the naturalist Roy Bedichek has written, and "Texas is certainly the most fence-conscious state in the Union . . ." For all its injury to nature, however, the fence has created a cultural resource of significance. Rights-of-way for rail and automobile traffic were securely fenced with natural growths still intact, preserving what Bedichek calls elongated "relic areas" that include nearly all the species present when Western man first occupied the country.

It may be that no other part of the world of comparable size equals Texas in its variety of native plant life. The state has virtually the whole range of plant life possible within the moisture limits of its latitude. Its shape even more than its great area causes this exceptional diversity through the broad range of natural conditions made possible by its peninsulalike extensions: the Panhandle, the Trans-Pecos, and the southward-pointing V-shape made by the meeting of the Rio Grande and the Gulf shoreline. Other causes of this variety are the climatic effects of the state's elevation range, its geographic position on the continent with respect to the Gulf of Mexico, the Mississippi Valley, and the Rocky Mountains, and one of the most complex and varied geologic systems in the nation, creating a wide variety of surface soils.

Various authorities have divided the state into different areas of native vegetation, but a division of 14 such areas is common. More than 36,000,000 ac. (14,569,200 ha.) are classified as forest land, of which nearly 11,000,000 ac. (4,451,700 ha.) grow commercial timber. Texas has about 225 tree types, but the most valuable commercially are the shortleaf, longleaf, and loblolly pines. The state has four national forests, with a gross area of more than 1,700,000 ac. (687,990 ha.) in the heart of the east Texas timber belt. In the Trans-Pecos Mountains are small growths of Douglas fir, piñon pine, Rocky Mountain white pine, and some varieties of western oak. Texas is the only state having native growths of both eastern and western pines and oaks. Desert vegetation of southwest Texas and the Trans-Pecos area includes the yucca, ocotillo, lechuguilla, candelilla, guayule, maguey, creosote bush, and several hundred varieties of native cacti. Some rare species of juniper grow in the Chisos Mountains. The 570 species of grasses found in Texas include nearly half of the varieties growing in the U.S., and the state has more than 4,000 different species of native wild flowers, some of which grow only in Texas. One of these is the bluebonnet, the state flower.

The area of chief botanical interest is the Big Thicket, an ill-defined area in the southern part of the east Texas forest region. The Big Thicket, largely unknown even to most Texans, is a giant wild garden, in some places almost impenetrable because of its junglelike growth, whose importance as a great botanical and wild life preserve is slowly being effaced by lumber and oil production. Covering about 2,000,000 ac. (809,400 ha.) of southern Polk and Tyler counties and northern Hardin and Liberty counties, the Big Thicket is a swampy land of mystery and myth. For more than a century it was a sanctuary for criminals, army deserters, and conscientious objectors of the American Civil War and World War I, but its considerable and unheralded significance is as a living botanical museum. The only remaining tribe of Texas Indians, the Alabama-Coushatta, lives on a reservation on the northern edge of the Big Thicket.

**Animal Life.**—The list of birds found in Texas includes nearly two-thirds of all species found in North America north of Mexico and many more than are found in any other state. It includes all species ever listed in the rest of conterminous U.S. between the Atlantic seaboard and the Rocky Mountains with the exception of about 20% of those found in Florida and the same percentage of those occurring along the Canadian border. The great flyways of North American birds lie between the Appalachian and the Rocky mountains and except for one considerable leak near the mouth of the Mississippi, the low-flying, easily winded species are herded through Texas in their migrations. Of the more than 800 kinds of birds found in Texas, 42 are permanent residents, 225 are winter residents, and 70 are summer residents. The others are transients that stay only long enough to rest during migrations.

The lowlands of the Texas coast are unrivaled in the U.S. for bird scenery, not only for bewildering variety but also for abundance. This is notably true of the town of Rockport, near Corpus

Christi and the centre of the Aransas National Wildlife Sanctuary. The attention of the Western world has been drawn to the tragic circumstance of the whooping crane, which is making its last stand in the Aransas Sanctuary. But a famous game bird, the prairie chicken, is also on the verge of extinction only a few miles inland. The prairie chicken has been endangered by the gradual assumption of its habitat for rice farming, and by poison sprays used to kill the boll weevil, important in the bird's diet. Besides the Aransas preserve, Texas has four other national wildlife refuges, several state refuges, and six Audubon Society preserves, including South Bird Island in the Laguna Madre, one of the two U.S. winter havens for the white pelican.

Nearly half of the nation's wild turkeys, the state's most prized game bird, occur in Texas, and fossil evidence indicates that it is one of the state's oldest inhabitants. Ducks, geese, and quail are the other game birds of importance.

Native mammals of importance to Texas for various reasons are several species of deer (especially the white-tailed, or Virginia, deer), the chief game animal; several furbearing animals of commercial value; and four species of coyote, destructive but much maligned predators and subjects of considerable folklore. Virtually curiosities in the 20th century are three mammals whose extinction in Texas has been slowed by belated conservation procedures. The American bison, or buffalo, largest of native North American mammals, once lived on the Texas plains in tremendous numbers; long before the second half of the 20th century the only bison in Texas, outside zoos, were bred on a few ranches as a hobby. Texas bighorn sheep and the pronghorn antelope were once common in the state, as was the prairie dog, one animal that is not conserved. More than 400,000,000 prairie dogs once lived in a single colony in west Texas and hundreds of millions lived throughout the region, but by the 1960s their numbers had dwindled to only a few hundred in widely scattered areas. The prairie dog was systematically poisoned by the federal wildlife service and by ranchers because of its destruction of range grasses, its principal food.

All four of the poisonous snakes of the U.S. (copperhead, water moccasin, rattlesnake, and coral snake) and perhaps a third of the nation's harmless snakes are found in Texas. The alligator is fairly common in east Texas rivers and lakes.

A small lizard, the horned toad, is a commonplace of Texas that is a subject of myth and folklore. Some other subjects of folklore are a bird, the chaparral, also called paisano and road-runner; a mammal, the nine-banded armadillo; and a poisonous insect, the vinegarroon, or vinegarone, a whip scorpion found in southwest Texas, whose power to injure is much less than that attributed to it by border legends.

The Texas coastal waters produce the Atlantic and Gulf South's greatest harvest of shrimp, which constituted about half of the entire Texas Gulf marine crop. Although the state's oyster crop has declined, it continues to be of importance as a marketable food commodity and of even more importance as a source of shells, providing lime for the petrochemical industry. Saltwater fishes of commercial value are red snapper, redfish, saltwater trout, drum, grouper, whiting, flounder, and mackerel. Between 200 and 250 species of fish are found in the bays and offshore coastal waters of Texas and about 200 species of freshwater fish are found in the state.

**State and National Parks.**—The Big Bend National Park takes its name from the huge U-turn made by the Rio Grande 200 mi. (322 km.) SE of El Paso. Natural life ranges from subtropical cacti in its arid basins to Douglas fir trees on its 8,000-ft. (2,440-m.) Chisos, or Phantom, mountain range. In the deserts live peccaries and rare hummingbirds; in the mountains are lynx and eagles. The park (697,981 ac. [282,473 ha.] owned by the U.S.) was established in 1944 and includes desert, foothills, mountains, and river valley. The three precipitous canyons of the Rio Grande are the Boquillas, Mariscal, and, the deepest, Santa Elena, 1,500 ft. (457 m.). Emery Peak, of the Chisos Range, is the highest elevation in the park (7,835 ft. [2,388 m.]).

Padre Island National Seashore was established by the National Park Service in 1962. It comprises 80 mi. (130 km.) of barrier

beach between Corpus Christi and Port Isabel.

The Mission San José de San Miguel de Aguayo (Mission San José), at San Antonio, is the only national historic site in Texas it is owned by the state and is also a state park. Texas had 50 recreational and historical state parks in various stages of development in the 1960s. Compared with the state's vast area, however, the number and extent of its parks are not great. Scenically, the most rewarding are the Davis Mountains State Park in the Trans-Pecos region, and the Palo Duro Canyon State Park in the Panhandle.

Of larger interest and importance are the Spanish missions of San Antonio, El Paso, and Goliad, some of them state parks. One of these, in midtown San Antonio, is the most famous monument of Texas: the Alamo, which means "cottonwood" in Spanish, was the church for Mission San Antonio de Valero. The present structure, the second on the site, was begun in 1758 but never completed. Following the meandering course of the San Antonio River southward from the city is the Mission Road, which leads to four Spanish missions founded at the city in the early part of the 18th century.

The four are the missions Nuestra Señora de la Purísima Concepción de Acuña (Mission Concepción), San José, San Juan Capistrano, and San Francisco de la Espada. By far the most important is the Mission San José. The present church, begun in 1768, is the finest of Texas missions, and even in the 18th century the Spaniards called San José "the queen of missions." In time it became the largest and the most prosperous, and the intricate, baroque beauty of its facade and baptistry window, carved by the Spaniard Pedro Huizar in two periods totaling 18 years, makes it one of the chief architectural treasures of the U.S.

The Mission Concepción (c. 1735), 2 mi. (3.2 km.) N of San José, is the best preserved Texas mission. Ninety miles southeast of San Antonio, at Goliad, is the modern restoration of the Mission Nuestra Señora del Espíritu Santo de Zúñiga and, more important, the chapel of the Presidio Nuestra Señora de Loreto de la Bahía (La Bahía). The presidio chapel is original and ranks architecturally with the missions of San Antonio. La Bahía has the additional advantage of a commanding site on a hill that overlooks a cultivated valley. Other Texas missions, including earlier missions near El Paso, are mainly modern reproductions or restorations.

The Spanish Governor's Palace in downtown San Antonio, completed in 1749, is also a modern restoration but a superb and important one. The palace was not the official residence of the governor of the Province of Texas but the residence of the presidential captain, who was, in the absence of the governor, the ranking representative of the king of Spain. It became known as the Governor's Palace long after it was built. Another restoration from the Spanish period in midtown San Antonio is La Villita (the Little Village), a sharp contrast to the elegance of the Governor's Palace. The little adobe houses were occupied in the 18th century by soldiers and their families of the Presidio San Antonio de Bexar.

## HISTORY

Man has been traced through 15,000 years of the state's prehistory, but historically—the time in which people of European origin have known the land that became Texas—the state's history began early in the 16th century.

**Exploration and Settlement.**—The Spaniard Alvar Núñez Cabeza de Vaca opened this period when he and three companions, sole survivors of a wrecked ship, washed up on the Gulf Coast in 1528. Years later he wrote an account of this adventure, the first written record of the land. Within two decades Francisco Vázquez de Coronado and the followers of Hernando de Soto, searching for mythical cities of gold and gems, explored parts of Texas. The first settlement in Texas was made in the extreme western part of the state, near El Paso, in 1682, an accident of fate for which the Indians of New Mexico, revolting against Spanish rule, were responsible (see EL PASO). The next settlements were made in the extreme eastern part of Texas, in 1690, when French designs on the land aroused the Spanish to establish missions there.

In 1685 René Robert Cavelier, sieur de La Salle, explorer of the Mississippi, sailed from France with a small fleet to establish a colony at the mouth of the Mississippi. He missed the mouth of the river, perhaps deliberately, and with remnants of his unlucky expedition managed to establish a small colony near Matagorda Bay on the Texas Gulf Coast. Within two years La Salle had been slain by his own men and most of the members of his colony had perished. Before the century closed the Spanish missions in east Texas were hard put to cope with the increasing hostility of the Indians, and the missions were abandoned. For a brief time most of Texas then remained virtually unoccupied. Indeed, the Spanish were remarkably complacent about their claim to Texas throughout the 18th century, though an incident in 1714 briefly spurred them again and for the most part ended the influence of French aspirations on Texas. That was the appearance in Texas of the French explorer Louis Juchereau de Saint Denis, causing the Spanish to establish what proved to be permanent settlements at San Antonio, Nacogdoches, and Goliad. By 1800, when the three places were the only ones in Texas that could be called towns, the number of settlers in the future state was perhaps 7,000 but probably less. The events of Texas history, however, were to proceed swiftly after the early 1800s.

**Revolution and Republic.**—For three centuries after Cabeza de Vaca the land belonged to the Spaniards, then to the Mexicans for a brief interval (1821–36), and afterward to Americans. Mexico, of which Texas was a part, won its independence from Spain in 1821. Late that year 300 American families, led by Stephen F. Austin, 28-year-old heir to the dreams of his father, Moses Austin, began colonizing land granted by Mexico. Other groups followed until perhaps 30,000 Americans, four times the number of Mexicans, were living in Texas by 1836. The Mexican government, though suspicious of the burgeoning American population in Texas, was unable to cope with it while contending with its own spasms of revolution and a rapid succession of administrations. The American colonists got their land from Mexico, but their different language and culture caused them to shun the republic. Mexico tried in vain to discipline the colonists. It abolished slavery, it levied duties, it established military garrisons, and at last it declared martial law and tried to disarm the Texans. Inevitably, fighting erupted at several points, notably at Gonzales on Oct. 2, 1835, when the Mexicans were repulsed in the first battle of the Texas revolution.

Meeting at San Felipe on Nov. 3, Texans formed a provisional government but could neither agree to declare their independence nor on much else; this want of unity was to continue with tragic consequences. In December San Antonio was captured from the Mexicans, who agreed to withdraw to Mexico. That was the

Texans' last victory until the final battle more than three months later. On March 2, 1836, when the Mexican dictator Antonio López de Santa Anna (*q.v.*) had recaptured San Antonio and was closing in on the Alamo's few defenders, Texans meeting at Washington-on-the-Brazos declared their independence, established the Republic of Texas, and elected David G. Burnet provisional president. Command of the army was given to Sam Houston (*q.v.*), formerly a U.S. congressman and governor of Tennessee, who is the most remarkable figure in Texas history.

It would be hard to conceive of a more tragic or more heroic beginning for a new nation than the Battle of the Alamo. When the siege began on Feb. 23, the Alamo (*q.v.*) was defended by 150 men, including David Crockett, James Bowie (*qq.v.*), and Col. William B. Travis, the commander. On March 1 a reinforcement of 32 men succeeded in slipping through Santa Anna's lines, but further reinforcements were prevented by confusion and dissension in the provisional government. By March 4 the 182 Texans were besieged by about 4,000 Mexicans. Defying Santa Anna's demands for surrender, the Texans fought their hopeless battle until March 6, when Santa Anna assaulted the Alamo on all sides and overwhelmed the defenders. The last Texans perished in hand-to-hand fighting inside the Alamo. Subduing the 182 defenders cost the Mexicans between 1,000 and 1,600 lives.

After the Alamo fell, Col. James W. Fannin, commanding 300 men at Goliad, was ordered to retreat. He was finally able to do so on March 19 but was overtaken by the Mexicans that afternoon. Greatly outnumbered, he surrendered after a hopeless battle, and the Texans were returned to Goliad. On March 27, at Santa Anna's order, Fannin's entire force was slaughtered in cold blood. The battle of the Alamo and the Goliad massacre gave the Texans a battle cry when the two forces met for the last time: "Remember the Alamo, remember Goliad!" The Battle of San Jacinto, a brief, bizarre climax to the revolution, was fought on April 21 on the San Jacinto River, near the site of what was to be the city of Houston. After days of retreat, General Houston defeated the larger force in a surprise attack during the Mexicans' siesta. Six hundred Mexicans were killed and 200 wounded during the 20-minute battle. Santa Anna (later freed) and 700 others were captured in 24 hours. Fewer than a dozen Mexicans escaped. Of the 800 Texans in the battle, nine were killed and 30 wounded.

The historian Andrew Forest Muir has shown that most of the Texans who were killed at the Alamo, murdered at Goliad, or fought at San Jacinto had never been in Texas before the first weeks of 1836, and that most of the men who had lived in Texas before the revolution chose not to join the army. Few of the exact details of the whole revolutionary campaign are generally agreed upon, and even more are the details of the last, decisive battle

disputed or unknown. The Battle of San Jacinto, Muir wrote, "is the most controversial event in all of Texas history."

**Annexation.**—The new nation endured perilously for a period of almost ten years. After Texas was annexed by the U.S., technically on Dec. 29, 1845, but in fact on Feb. 19, 1846, a war with Mexico ended the contest for the land. It had been a melancholy contest.

Time and again the U.S. had spurned the land. Aaron Burr (*q.v.*) was the first to go after it. But Thomas Jefferson, embittered by Burr's rivalry for the presidency in 1800 and head of a nation rich in the new lands of the Louisiana Purchase, was little concerned whether the nation's western boundary was the Sabine or the Rio Grande. Between the rivers was Texas, claimed but not

## VOLUNTEERS!

### Men of the Granite State!

Men of Old Rockingham!! the granberry-bred of patriotism, renowned for bravery and devotion to country, rally at this call. Santa Anna, recking with the generous confidence and magnanimity of your countrymen, is in arms, eager to plunge his traitor-dagger in their bosoms. To arms, then, and rush to the standard of the fearless and gallant CUSHING—put to the blush the dastardly swariness and rank torporism of Yankee-balls. Let the half-civilized Mexicans hear the crack of the quivering New Hampshire rifleman, and illustrate on the plains of San Luis Potosi, the fierce, determined, and undaunted bravery that has always characterized her sons.

Col. THEODORE F. ROWE, at No. 31 Daniel-street, is authorized and will enlist men this week for the Massachusetts Regiment of Volunteers. The compensation is \$10 per month—\$30 in advance. Congress will grant a handsome bounty in money and ONE HUNDRED AND SIXTY ACRES OF LAND.

Portsmouth, Feb. 2, 1847.

War with Mexico: (left) the Alamo, an 18th-century mission chapel in San Antonio, defended to the death by Texans against vastly superior Mexican forces, Feb. 23–March 6, 1836; (right) 1847 poster urging New Hampshire volunteers to fight in the Mexican War

quite secured by Spain, and there Burr dreamed of creating a new American frontier. His dream came a cropper when he was betrayed by a cohort and ruined by Jefferson. A decade later the land was again rebuffed when James Monroe, trading for title to Florida, relinquished to Spain America's claim to Texas. Next Andrew Jackson schemed with his friend Sam Houston to get the land for the U.S., and gradually Texas became one of the great political issues of the time. Opposing Pres. John Tyler's hope of taking Texas into the nation, Daniel Webster resigned as secretary of state. The issue was not so much Texas as slavery: Texas would be another slave state. Sam Houston hurried toward his goal of annexation by pretending to deal with Great Britain. The British, though they had no wish to acquire Texas, opposed annexation by the U.S. and at one time thought of using force to prevent it. The U.S. Congress, fearing Britain's motives, narrowly approved annexation in 1845.

The slavery issue caused the rise of virulent antipathy toward Texas. Typical were the publications, in the early 1840s, of the Anti-Texas Legion, whose name was so spelled for reasons of abuse. Hale's pamphlet (*see above*) cited six dangers of admitting Texas to the union, two of which were not unheard of a century later. Admit Texas to the union, Hale wrote, and the U.S. would have "The introduction into the union of an unprincipled population of adventurers, with all the privileges of a State of naturalized citizens," and "The creation of an enormous State, in time to become the real Empire State of the country."

Frederick Law Olmsted, in *A Journey Through Texas*, the second volume of his southern trilogy of the 1850s, opposed the charge, common at the time, that the U.S. got Texas through guile: "We saw the land lying idle; we took it. . . . When the history [of the state's rebellion, independence and annexation] is candidly read, the story that the whole movement was the development of a deliberate and treacherous plot for the conquest of Texas, appears a needless exaggeration of influences that really played a secondary part. . . . The land was fertile; that was the kernel of the matter." (Olmsted was one of the first to take notice of a Texan trait that was to become better known, and more objectionable to others, in the next century: "So anxious is every one in Texas to give all strangers a favourable impression, that all statements as to the extreme profit and healthfulness of lands must be taken with a grain of allowance. We found it very difficult, without impertinent persistence, to obtain any unfavourable facts.")

**Confederacy.**—Sam Houston, hero of the revolution, twice president of the republic, loved and loathed by the people, who divided for and against this expert at controversy, was elected to the U.S. Senate soon after Texas was admitted to the Union. He was replaced in 1859, after nearly 14 years in the Senate, when the Texas legislature took revenge for his belief that the Union should be preserved and refused to reelect him. ("I make no distinction between southern rights and northern rights," Houston said late in 1858. "Our rights are rights common to the whole Union.") In an astonishing proof of his powers, he was then elected governor without silencing his appeals for unity before an electorate that yearned for secession. His unfinished term as governor was to be a dismal end to his career. A little more than a year later, after the people of Texas spurned his pleas for national unity by voting to secede from the U.S., Houston was deposed. He retired to his farm and died two years later.

**Reconstruction and After.**—The state's role in the Confederacy and the Civil War was not important except as a supplier of men, material, and services. But it paid a large price during the excesses of Reconstruction. Texas was the ninth state in the nation in per capita wealth in 1860; in 1880, seven years after Reconstruction ended in Texas, it was 36th. Texas was one of the last Confederate states to be readmitted to the Union (1870), but radicals controlled the state until 1873. Livestock and railroad interests dominated the state between Reconstruction and the end of the century. In 1901, when the Spindletop oil gusher blew in at Beaumont, oil began more than half a century of dominance.

The great governor of modern Texas history was James Stephen Hogg, a progressive, who was elected in 1890 on a platform promiss-

ing regulation of corporations but especially of railroads, which he had disciplined earlier as attorney general. The most important reform of his two terms was the creation of the Texas Railroad Commission. The commission later became the most influential state regulatory body in the U.S. when control of oil production was added to its powers. A large man in character and physique, Hogg's altruistic influence was effective for nearly 20 years. Three other but very different political figures abused and for long periods influenced the state during the first half of the 20th century. James E. Ferguson, impeached as governor in 1917; his wife Miriam A. Ferguson, afterward twice governor; and W. Lee O'Daniel, twice governor and twice U.S. senator. The flamboyance and rural demagoguery of this trio gave an additional dimension to the state's reputation for eccentricity. Texas's first Republican senator since Reconstruction, John G. Tower, won a special election in 1961 and was elected to a full term in 1966.

In and out of the state, the singularities and the chief interests of Texas history are the years of Spanish-Mexican and Anglo-American colonization, the revolution of 1836, and the decade of independence.

## GOVERNMENT

The Texas constitution, adopted in 1876, is one of the longest and least efficient of the state constitutions, and it may be the most frequently amended. A charter of nearly 50,000 words, including, in the 1960s, more than 150 amendments, it contains much statutory material, a contradiction of the principles of constitutional law. Both the state's constitution and statutes have long been the subjects of reform movements.

**Legislature.**—The constitution, which makes the legislative branch of government far more powerful than the executive and judicial branches, reflects the suspicion and fears of radical domination during Reconstruction. Texas government is believed to be more dominated by its legislature than that of any other state. The legislature, composed of 31 senators and 150 representatives, convenes biennially in odd-numbered years. Special sessions may be called by the governor.

**Executive.**—A governor and a lieutenant governor head the executive branch. The chief power of the governor, whose veto can be overruled by a two-thirds vote of both houses of the legislature, is appointive, an influence gradually and formidably enlarged throughout the first half of the 20th century. The governor appoints certain individual officers and commissioners of state government and the members of most of the 175 state boards and commissions. The elective officers of state government are the governor, lieutenant governor, attorney general, comptroller of public accounts, treasurer, commissioner of the general land office and commissioner of agriculture, each selected for a two-year term, and the three members of the Texas Railroad Commission, elected for six-year overlapping terms.

**Judiciary.**—The entire Texas judiciary, which is divided into three levels, is elective. At the top are, in effect, two supreme courts. One (nine members) is so called and has jurisdiction in civil law. The other (three members and an appointed commissioner of two) is the court of criminal appeals and has jurisdiction in criminal law. Texas is one of only two states still having separate "supreme" courts for civil and criminal cases (the other is Oklahoma). The second level of the judiciary are the 11 courts of civil appeals (three members each). The 150-odd district judges comprise the third level.

**Finance.**—Although Texas has no income or corporation taxes, it has had a 2% general sales tax since 1961. Other substantial revenues are derived from taxes on the state's enormous production of oil and natural gas plus a heavy sales tax on cigarettes and gasoline. A report made in 1950 by the Texas Legislative Council, the research agency of the legislature, showed that 36% of the state government's annual revenue came from direct taxes on petroleum and its products and from such other petroleum sources as royalties, leases, and bonuses. An amendment to the state constitution approved in 1942 gives the comptroller the power to veto, in effect, any appropriation of the legislature that exceeds anticipated revenues.

## POPULATION

The population of the area that was to become the state of Texas seems to have been between 6,000 and 7,000, few of whom were Anglo-Americans, at the opening of the 19th century. Figures on the growth of the population in the first half of the century are questionable, but by 1850, the date of the first federal census, the population was 212,592, ranking 25th among the states. In the following decade the population made its greatest proportional

increase (184.2%) to 604,215 in 1860. The growth of the population was slowed by the American Civil War and Reconstruction, but in the 1870s the population made its next greatest proportional increase (94.5%) to 1,591,749 in 1880. In 1900 the population was 3,048,710, ranking sixth among the states. Texas was to rank fifth in population in 1910, 1920, and 1930, when it was overtaken by California; thereafter it ranked sixth. The census figures, and the percentages of increase over the preceding census, for the first

Note: Dash indicates place did not exist during reported census period, or data not available.

half of the century were: 1910, 3,896,542 (27.8%); 1920, 4,663,228 (19.7%); 1930, 5,824,715 (24.9%); 1940, 6,414,824 (10.1%); 1950, 7,711,194 (20.2%); 1960, 9,579,677 (24.2%). Population density was 36.4 persons per square mile in 1960, far below the population density (49.6) of the U.S.

By the middle of the 20th century the character of the population was undergoing a quick metamorphosis that created a formidable contention within the state: in the ten years between 1940 and 1950 Texas changed from a predominantly rural to a predominantly urban state, bringing about a shift in character, attitudes, and aspirations that continued through the 1960s. Though the rural-urban conflict is old to most American states, it arose suddenly in Texas and with more effect than in many states.

People moving into Texas moved to the cities, which was to be expected. What multiplied the cities' peril was that masses of people from the state's rural areas also moved to the cities in the decades of the 1940s and 1950s. While population filled the cities, rural Texas was being drained. Thus, through the undemocratic process imposed by the rural bloc and certain urban elements in sympathy with it, the burgeoning cities came to have the majority of votes by the late 1940s but the comparatively deserted rural areas had the majority where it counted—in the legislature. The exodus from rural areas is a national phenomenon with common causes, but in Texas it was also impelled in other ways. The long drought ending in 1957 and the decline in cotton cultivation caused by the loss of foreign markets were large influences in forcing the state's farm tenants into the cities.

In 1956, 87% of the state's surface was farm and ranch land with a population estimated at 950,000. The remaining 13% of the surface was urban, its population estimated at 7,707,000. The state's twenty-one metropolitan areas (more than those of any other state but by no means all of urban Texas) alone contained a majority of Texans by 1958. The speed of the state's population shift concealed some of its dangers in the more gradual national trend. In 1934, 40% of the state's population was on the farm; 20 years later the figure had shrunk to 13%. From 1930 to 1954 the state's farm population declined by 52%, nearly twice as much as the national decline of 28%. In the decade following 1945 Texas lost farm population more than twice as fast as did the nation (28% to 12%). Between the federal censuses of 1940 and 1950, 108 Texas counties gained population, but 146 counties lost. In that decade the state's urban population jumped 66%, and by 1950 Texas was 62.7% urban compared with 64% for the nation; by the 1960 census the figure was 75%, compared with the national 69.9%.

In 1960 the white population of Texas was 8,374,831; the non-white population was 1,204,846, of whom 1,187,125 were Negroes. In every census from 1870 to 1960 the population showed a decline in the percentage of Negroes, who were 14.4% of the population in 1940 and 12.4 in 1960. The Latin-American (Mexican) population in 1960 was 1,417,811, or 14.8% of the total.

Texas was fancied to be filling with newcomers from the north after World War II, recalling Edward Everett Hale's plea, in 1845, for "the North (to) pour down its hordes" upon Texas. But through 1960 the surge in the state's population did not come from outside the state. Texas has always been at least three-quarters full of Texans. The state's increasing population was due to a high proportion of births over deaths and even more to Texans' reluctance to leave Texas. The population increased by 1,868,483 between 1950 and 1960, but only 113,831, or about 6% of the total increase, were added by the excess of newcomers over people who left the state. In 1960, 76% of the population was born in Texas.

Texas was thought to be filling with northerners when oil and industry overtook agriculture's economic dominance. Such thinking had some substance in the larger cities, but for Texas as a whole it was a delusion at the time of the 1950 census, when most newcomers were from next-door states. The 1950 census showed that more newcomers came from Oklahoma than from any other state, followed by Louisiana and Arkansas. For nearly a century the mutual concern for cotton attracted southerners to the state; it was the South that poured down its hordes upon Texas. Although the 1950 census showed that natives of all northern states nearly equaled those of the South in Texas, by the 1960 census the south-

erners outnumbered the northerners by three to two.

Despite the extravagance of newspaper and magazine reports about the state after World War II, Texans are similar to newer-model Americans anywhere. Until the 1950s and 1960s, however there was the difference that broader opportunity had enlarged those traits common to areas of new chances and new methods. The traits are characteristic of frontiers, where goals are often personal rather than civic—the acquisition of wealth and identity to the exclusion of aesthetics and reforms. A frontier in spirit need not have the rusticity of a Wild West movie; it can have skyscrapers and symphony orchestras. But by the 1960s the frontier spirit was much diminished as a characteristic of the state's population.

## EDUCATION

Both the republic and the state of Texas set aside public lands for the support of state institutions. The chief beneficiaries have been the public schools, the University of Texas and the Agricultural and Mechanical University of Texas. The amount of the permanent school fund (public schools) by the 1960s was more than \$400,000,000, one of the largest endowment funds in the nation. The amount of the university permanent fund, from which two-thirds of the income goes to the university and one-third to A. & M. University, was nearly \$330,000,000. Petroleum was again the chief contributor: by the end of 1956 oil bonuses, lease rentals, and royalties had contributed more than \$500,000,000 to the two funds. By the late 1950s oil, gas, and sulfur leases in the Texas tidelands, ownership of which the state had earlier disputed with the federal government, had contributed more than \$70,000,000 to the permanent school fund. The state set aside a total of nearly 52,000,000 ac. (21,044,400 ha.) to benefit education, but the two great funds are mainly the result of grants made by the constitution of 1876. More than 42,000,000 ac. (16,997,750 ha.) were given to the public schools and 2,100,000 ac. (849,900 ha.) to the university fund. Most of the public school land was eventually sold (and the mineral rights retained), the proceeds going to the permanent school fund, but the university land is intact.

**Public Schools.**—The 100th anniversary of the Texas public school system was observed in 1954. The public schools are administered by the State Board of Education, which consists of 21 members elected by popular vote in 21 districts. The public schools are mainly financed by an ad valorem tax, by a fourth of certain revenues (principally the gasoline tax), and by income from the permanent school fund. Each school district builds and equips its own schools. Historically, separate school systems were maintained for Negroes and in some districts for Latin Americans. Following the U.S. Supreme Court decision in 1954 voiding the segregation laws of the Southern states, some schools abolished segregation. By the 1960s most districts had desegregated or had started integration on the so-called stair-step basis.

**Higher Education.**—Fifty-two junior colleges, colleges, and universities are supported in whole or in part by the state. Of these the larger are the University of Texas (1881), at Austin, the first state-supported school in Texas to require entrance examinations; Texas A. & M. University (1876), at College Station; Texas Technological College (1923), at Lubbock; North Texas State University (1890); Texas Woman's University (1901), both at Denton; and Texas Southern University (1947), at Houston.

The University of Texas was founded in 1881 after the state constitution of 1876 directed the legislature to establish a "university of the first class." It has branches at Galveston, Dallas, Houston, and San Antonio and includes Texas Western College, at El Paso. In spite of the university's two-thirds share in the enormous endowment fund resulting mainly, since 1923, from the production of oil on its land, its reputation for wealth is largely a myth. By 1958, 4,085 oil wells on university land were producing more than 41,000,000 bbl. of oil a year, but not only does A. & M. University receive a third of the proceeds but each school may spend only the income on the money. A. & M. University, the oldest state-supported college in Texas, was founded in 1876. A military land-grant college for men only, it contributed more officers to the U.S. armed forces of two world wars than any other

The Texas economy: (far left) the approaches to Dallas, the state's second largest city and financial centre; (centre left) aircraft manufacturing, an important sector of the industrial economy, near Fort Worth; (above) cowboys and cattle raise dust on roundup near Waco; (right) oil refinery near Dallas symbolizes a major industry

college or university. Its enrollment in the 1960s was in excess of 7,000. The University of Houston (1934) became a state-supported university in 1963.

Chief among the independent colleges and universities are Rice University (1912), at Houston; Southern Methodist University (1911), at Dallas; Baylor University (1845) (Baptist), at Waco; and Texas Christian University (1873), at Fort Worth.

### HEALTH AND WELFARE

Expenditures for health and hospitals rank high among the states. The Texas State Department of Health administers health laws, rules, and regulations. Tax-supported eleemosynary institutions include hospitals for mental patients, tuberculosis hospitals, schools for the blind and the deaf and for mentally retarded and cerebral palsied children, and adult mental health clinics. Old age and other public assistance programs are administered by the State Board of Public Welfare. Expenditures for old-age assistance and for assistance to dependent children, to the blind, and to the permanently and totally disabled are relatively high among the states. Maximum workmen's compensation and average weekly unemployment benefits are relatively low.

### THE ECONOMY

Early in the decade following World War II, the time of greatest change in Texas since the revolution more than a century before, Texas became synonymous with the word "millionaire" or, more often, the phrase "oil millionaire." That it was so known to others became a burden of surprising weight by the early 1950s; that many Texans came to believe the legend was a burden of even more consequence. In time some Texans came to loathe the myth, one conceived by periodicals and newspapers from the adventures and eccentricities of exhibitionists and influence seekers. Facts denied the myth, but facts could do little to overcome the myth once it was fixed in the public mind. Yet the state with a reputation for riches was 26th among the U.S. states in per capita income in 1955 and 1956 and dropped to 27th in 1957. In 1959 the median income of Texas families (\$4,884) was around \$670 lower than the median income of all families in the U.S.

The single reality of the state's reputation for riches was phi-

lanthropy, large-scale spending for the public good, whose effect on the economy was trivial at first but whose future was stunning in the 1960s. Texas exempts from taxation only foundations whose spending is kept within its borders, thus causing most Texas foundations to limit their interests to the state. In 1955 Texas foundations, mainly resulting from oil fortunes, were fifth among the states in assets, seventh in expenditures, and seventh in grants, positions roughly comparable to the state's rank in population. But the number and size of Texas foundations grew swiftly in the later 1950s, during which time some of the state's largest were established.

For almost a century Texas was a reservoir of raw materials within the U.S. economy. Texas took from the land oil, cotton, beef, and other goods and exported them to industrially more advanced states for final processing. One of the most notable changes in Texas following World War II was its shift from a raw-materials economy to an industrial economy, a metamorphosis by no means completed in the 1960s. After World War II Texas developed suddenly in a way that northern states had developed for more than half a century. But Texas had the extra impetus of extraordinary reserves of certain natural resources, notably oil and natural gas.

**Agriculture.**—Because of its large area and the diversity of its agriculture, Texas is agriculturally a miniature of the nation as a whole. Historically (until the discovery of major oil deposits early in the 20th century), cotton and cattle were the chief elements of the state's economy, and both remained large elements in the second half of the 20th century. Texas traditionally leads the states in growing cotton and raising cattle.

As a rule during the 1950s and 1960s Texas was first in the production of cotton, rice, sorghum grain, sorghum forage, other hay, cowpea hay, and cowpeas (for peas); second in the production of pecans, grapefruit, and grain hay; third in the production of oranges, broomcorn, and vegetables (but first in beets, spinach, watermelons, winter cabbage, winter carrots, early fall carrots, winter cauliflower, spring honeydew melons, early spring onions, and early summer onions); fourth in the production of winter wheat (but sixth when combined with spring wheat), peanuts (for nuts), peanut vine hay, and sorghum silage; and fifth in the pro-

duction of sweet potatoes and honey. It was first in the number of cattle, sheep, lambs, horses, and mules; first in the production of wool and mohair.

In one year of the late 1950s Texas produced 37.6% of the nation's cotton lint, 38% of its cottontseed, 25.4% of its rice, 10.3% of its fresh vegetables, 9.8% of its grapefruit, and 44.4% of its sorghum grain. The state had 8.8% of the nation's cattle, 16.4% of its sheep and lambs, and 7.5% of its horses and mules. It produced 96.9% of the nation's mohair and 16.1% of its wool.

A number of changes besides farm mechanization and soil conservation substantially affected Texas agriculture after the depression of the 1930s. Between 1930 and the 1960s the state's farm population declined from a peak of 2,342,553 to perhaps less than 1,000,000 (from 42% of the total to around 10%). In the same period the average size of the state's farms increased from 251.7 ac. (101.9 ha.) to more than 500 ac. (202.4 ha.). Farm tenantry declined during the period, and share-cropper tenantry declined from 105,122 in 1930 to well under 10,000. And the areas of cotton production and cattle raising shifted during the period. The principal area of cotton production moved from the prairies of central Texas to the south Gulf coastal plain and west Texas, drawn mainly by irrigation. The principal area of cattle raising moved from west to east.

**Industry.**—Texas industrial production exceeded mineral production for the first time in the decade 1947–57, and toward the close of the decade the state could at last be said to have an industrial economy of consequence. In the one decade Texas to some extent shed its historic colonial economy. In that ten-year period larger regional and national markets, the rise of capital investments in Texas industry and technological advances increased the state's industrial production 76% compared with a national increase of 43%. While total manufacturing activity more than doubled in Texas, that of the nation increased less than 50%. Among other effects of the rise of industrialism was that for the first time Texas was not so securely bound to the fate of one industry—petroleum.

The production of transportation equipment, increasing more than 300% during the decade, led the state's industrial gains except for the relatively small electrical machinery industry. Creating most of the growth was aircraft production in the Dallas-Fort Worth area. Another significant force in the state's new industrialism was the rise of primary metals production. The basic steel industry, established in Texas during World War II, expanded from a capacity of 582,230 tons in 1948 to more than 2,000,000 tons by 1960. The two basic steel plants are at Houston and in Morris County. A more spectacular development, however, was the establishment of three primary aluminum plants, in 1950–52, at Rockdale, Port Lavaca, and in San Patricio County. The only tin smelter in the U.S. is at Texas City. The production of oil field machinery and tools, mostly at Houston, was of importance, as it had been for more than three decades.

One of the most important aspects of the state's rise to industrial significance was the growth of the chemical industry in the Gulf Coast region. A dominant factor in this development was the increased production of industrial chemicals from oil and natural gas, and especially notable was the growing use of chemicals for making plastics and synthetic rubber. Development of the new industrial districts was planned with care. Factories were built away from residential and commercial areas. The spaciousness of the industrial areas contrasted sharply with the crowded, unhealthy factory districts of older industrial areas. Perhaps no area of the world had more of the raw materials needed by the chemical industry than the Texas Gulf Coast region, and none was the site of such dramatic expansion of the industry in the decade after World War II. Most of the chemical plants clustered around Houston, Corpus Christi, and the Beaumont-Port Arthur area.

The industrial complex of Houston and the upper Texas Gulf Coast was substantially enlarged in 1962 when construction of the Manned Spacecraft Centre was begun a few miles southeast of Houston at Clear Lake. The centre, a National Aeronautics and Space Administration project costing more than \$125,000,000, was established to direct the nation's manned spacecraft program

for the Mercury, Gemini, and Apollo projects—the conquest of the moon. Of larger importance economically, however, was the swift development of a type of industry new to the region—electronics—to work with the centre.

**Mining.**—Texas became the leading state in minerals production in 1935, increasing this production to roughly a quarter of the national total throughout the 1950s and 1960s. In Texas the word "minerals" means oil and natural gas, of which the state has almost half the nation's total known reserves. Next to oil and gas the most important of Texas minerals is sulfur, of which Texas and Louisiana together produce nearly 70% of the world's supply. Texas mineral production gained nearly 50% compared with a national gain of 28% in the decade 1947–57, but important oil discoveries elsewhere in the nation and the competitive pressures of foreign oil imports reduced the oil industry's rate of growth after the peak year of 1957. The production of crude oil, the state's largest single industrial output, dominates the state's mineral production and much else, but in the 1950s and 1960s the flow of crude oil increased at a slower rate than other types of mineral production and manufacturing. The production of natural gas and natural gas liquids, important exports to other states and even more important as fuel and raw material for Texas industries, increased rapidly.

The importance of the entire Gulf Coast as a petroleum refining centre is its tidewater exit for the largest oil production in the world. The Texas and Louisiana coast became the largest refining district of the U.S. in the 1950s, with about a third of the nation's capacity. Most of the Texas refineries are grouped around Houston and the Beaumont-Port Arthur area. In the 1960s water transport facilities were supplemented by the Houston-Beaumont to New York pipeline.

The Texas Panhandle, near Amarillo, is a major helium producing area. Production of the gas is controlled by the federal government because of helium's military significance. The plains of western Texas and southeastern New Mexico contain the nation's major supply of potash and one of the largest deposits in the world. Texas has large deposits of iron ore, which is used by its basic steel plants, and of lignite, used as a fuel by one of the state's aluminum plants. Throughout the 1950s Texas was a leading producer of carbon black, primary magnesium, bromine, and salt.

**Transportation and Communications.**—Inevitably, because of its area, Texas leads the states in highway and railroad track mileage. Of the more than 200,000 mi. (322,000 km.) of public roads in Texas in the 1960s, nearly 60,000 mi. (97,000 km.) were in the state highway system, of which nearly 55,000 mi. (88,500 km.) were paved. But because of the uneven distribution of the state's population, roughly 80% of the traffic traveled on 20% of the roads. Of the more than 21,000 mi. (33,795 km.) of railroad track, about 14,000 mi. (22,530 km.) were in mainline track. The state had nearly 700 airports, of which more than 30 were used by commercial airlines.

The 13 deepwater ports on the Texas Gulf Coast are artificial to varying extents. They are Houston, Galveston, Port Arthur, Beaumont, Orange, Corpus Christi, Brownsville, Texas City, Sabine Pass, Freeport, Port Aransas, Port Isabel, and Port Mansfield, of which Houston, Beaumont, and Port Arthur are inland ports. Houston, 50 mi. (80 km.) inland and connected with the Gulf of Mexico by the Houston Ship Channel, annually ranks between third and fifth of U.S. ports in commerce. The Texas section of the Intracoastal Canal runs the length of the Texas coast from Brownsville to Orange (and then eastward to meet the Mississippi at New Orleans). Thirteen shallow, or barge, ports are spaced along the Texas section of the canal. The 25 Texas ports are one of the state's chief economic benefits.

See also references under "Texas" in the Index.

**BIBLIOGRAPHY.**—The writing of Texas history had not produced a 1-vol. general work of excellence up to the 1960s. *The Texas Almanac*, published biennially by the *Dallas Morning News*, is the best general information source on the state. Texas State Historical Association, *The Handbook of Texas*, 2 vol. (1952); their *Southwestern Historical Quarterly* (1898– ) is more accurate.

The best work on the revolution, and a short one, is William C. Bink-

ley. *The Texas Revolution* (1952); the best one on the decade of the republic is William Ransom Hogan, *The Texas Republic* (1946). Two diverse works evaluating contemporary Texas are George Fuernmann, *Reluctant Empire* (1957) and Frank Goodwyn, *Lone-Star Land* (1955), virtually the only critical estimates of modern Texas.

Current statistics on production, employment, industry, etc., may be obtained from the pertinent state departments; the principal figures are summarized annually in the *Britannica Book of the Year*.

**TEXAS, UNIVERSITY OF**, a state-supported, coeducational institution of higher learning, founded in 1881 at Austin Tex. See TEXAS: Education.

**TEXTBOOKS.** Homer's poems were the first school textbook. Throughout the classical period these, often dictated because copies were scarce, supplied the schoolboy with material for his studies of language and literature, as also did Aesop and Hesiod. Rome added Virgil, Horace, and other great writers. Education was preeminently concerned with the study of excellent models.

The origins of the actual grammar book go back to a certain Dionysius whose grammar of the Greek tongue, produced in 120 B.C., set out the terms still used today. For science a variety of textbooks were produced in the Hellenistic period, chiefly by the scholars of Alexandria. To this period belongs Euclid's *Elements of Geometry* (c. 300 B.C.), a manual which in one form or another has been used down to modern times. As the Greco-Roman world advanced into the Christian era, however, the curriculum was predominantly literary. Yet some science remained. Nicomachus of Gerasa, for instance, produced about A.D. 100 an *Introduction to Arithmetic* that was widely used. But even astronomy, as likely as not, would be studied through the poetry of Aratus of Soli. Astronomy was one of the seven liberal arts that made up the senior curriculum; the others were grammar, rhetoric, dialectic, arithmetic, geometry, and music. In the 5th century A.D., the north African lawyer Martianus Capella embraced them all in a standard Latin textbook of theory and practice allegorically entitled *The Marriage of Philology and Mercury*.

In the Dark Ages, learning and piety were kept alive in the monastic schools, and scholars like Boethius (c. 480–524) and Bede (673–735) wrote textbooks for these institutions. Latin remained the key to learning. Aelius Donatus (q.v.), who taught in Rome in the 4th century A.D., wrote an elementary grammar so widely used that even in Chaucer's day, 1,000 years later, his name in the forms *donat* and *donet* was a synonym for a schoolbook.

Just as the spread of Greek culture took on speed when Livius Andronicus in the 3rd century B.C. translated Homer's *Odyssey* into Latin, so in the early centuries of the Christian era the relation of Latin to the vernacular became important. Bilingual textbooks were appearing by the 3rd century A.D. About the year 1000 in England, Abbot Aelfric produced a Latin grammar in Anglo-Saxon.

The revival of learning and the invention of printing gave a new impetus to the textbook. In Italy, Cardinal Bessarion (c. 1400–1472) published a Greek grammar. Erasmus, the Dutch humanist (c. 1466–1536), produced his *Colloquia* to supply the student with passages for his instruction, moral uplift, and delight. Coming to England he assisted William Lily to produce a Latin grammar for St. Paul's School, London. Now, increasingly, the great teaching orders of the Roman Catholic Church, such as the de La Salle brothers, brought out their own textbooks. In France the abbé François Fénelon (1651–1715, later arch-

bishop of Cambrai) taught Louis XIV's grandson, wrote history books, and directed attention to the schooling of girls. Meanwhile, in England, at the infant grade the hornbook persisted—a paddle of wood covered with transparent horn and setting out such elements of instruction as the alphabet, the Roman numerals, and the Lord's prayer (see HORNBOOK).

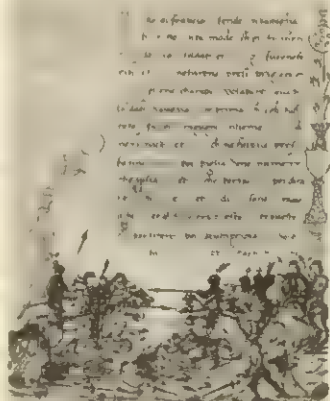

Increasingly, too, whole theories of education began to be reflected in the textbooks. J. A. Comenius (1592–1670), a Czech reformer with a comprehensive system whose fame took him to a number of countries including Sweden and England, was responsible for two celebrated schoolbooks. One, his *Gates of Language Unlocked*, gave sentence drill in Latin vocabulary with parallel translations in the vernacular. Written originally in Latin and Moravian it was subsequently translated into more than a dozen European and Oriental tongues. The English diarist John Evelyn (1620–1706) records that his son was well advanced in it by the age of five. More important was Comenius' *The Visible World in Pictures*, setting out lessons in the world of the senses and illustrated with woodcuts. Texts with pictures go back to Hellenistic times; but *The Visible World* is the real forerunner of the illustrated schoolbook of today.

In America the schoolbook was necessarily imported at first from England. The emphasis was on the spelling book and on the primer that would facilitate the reading of the Bible. A spelling book, however, had been printed in Massachusetts by 1650. *The New England Primer* was particularly popular. Isaac Greenwood of Boston wrote his *Arithmetick Vulgar and Decimal* in 1729. Noah Webster's *American Spelling Book* (1783) firmly established the United States as the home of its own textbooks.

The 19th century, with its new emphasis on popular education, brought a flood of schoolbooks and set up educational publishing on both sides of the Atlantic as a major part of the printing industry. In England the great textbook names began to emerge—Isaac Todhunter for mathematics, Sir William Smith for classical lexicography, the Rev. Benjamin Hall Kennedy for Latin primers, Henry Bradley for English dictionaries, and so on. In the United States William Holmes McGuffey (1800–73) compiled in 1836–37 his *Eclectic Readers*, moral in tone and varied in instruction, which were to dominate the scene and to sell more than 120,000,000 copies. But there were others, so that already by mid-19th century concern was felt in the United States at the proliferation of textbooks, and there were movements toward control. In England, Matthew Arnold as a school inspector reported scathingly in 1853: "Almost every educational society has its own schoolbooks. These are by no means universally adopted by the schools in connection with it, and a recognised textbook on any subject is nowhere to be found." Arnold could complain, too, of banality in the schoolbooks. Small children were taught to read such sentences as "The crocodile is viviparous." Nor was it always banality. Though, as with the McGuffey readers, a real attempt had begun to grade textbooks, they were often dull and uncompromising (in English boys' schools the quite unofficial *Kelly's Key to the Classics* was popular as a "crib"). They were sometimes worse. In *A Victorian Boyhood*, published by Macmillan and Co. Ltd. in 1955, Sir Lawrence Jones recalls "a thick blue *First Reading Book*, intended for very small children indeed, where the bones and blood of a child eaten by a wolf are described with a relish we lately reserved for the sinking of a German U-boat."

Some of the worst deficiencies of the 19th-century schoolbooks began to disappear as government or state inspection increased the efficiency of the schools. The spending of public money on textbooks, too, brought a demand for better standards. How far the state should control textbooks was a question that received, and continues to receive, different answers in different parts of the globe. But in English-speaking countries, at least, by the 20th century, the principle was emerging that the trained teacher was the person best fitted to choose his pupils' schoolbooks.

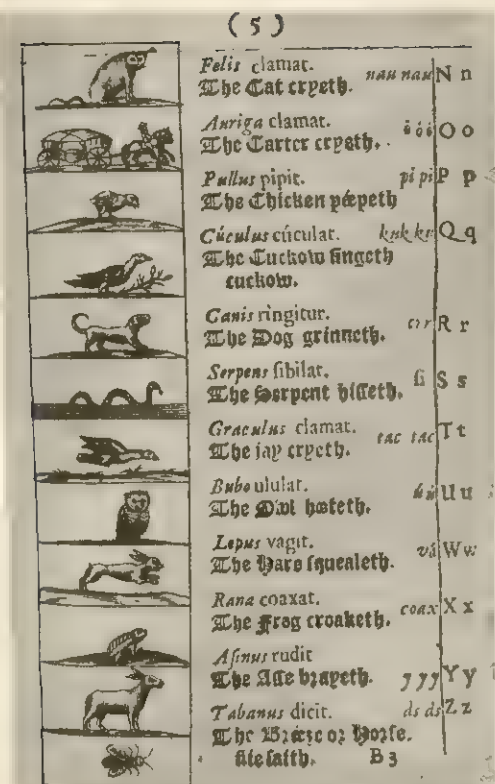

**Modern Period.**—In two-thirds of the countries of the globe the production of textbooks is left to private enterprise. Cooperation between makers and users of textbooks is increasingly practised, however, and bodies such as the National Book League in Britain and the National Education Association in the U.S.

The issue for the textbook is between a short, cheap life and a longer but expensive one. The content of the book sometimes makes possible a double issue—a paperback edition for the classroom and one with firmer covers for the school library. Paperback editions of advanced and hitherto expensive texts are becoming available with increasing frequency.

U.S. textbooks have been increasingly admired in Great Britain since World War II for their opulent production, splendid illustrations, and fresh approach to traditional subjects. Their high cost, however, has made them more often a stimulus for the teacher than a tool for the child. Nevertheless, *Latin for Today*, a course of U.S. origin, has done a great deal to wrest the English grammar school from its narrowly academic approach to the classics.

Bias in textbooks, particularly in those for history, has become a matter of much international concern. After World War II even the arithmetic books in Germany were found to be tainted with Nazi propaganda. United Nations Educational, Sci-

entific and Cultural organization (UNESCO) has been active in the campaign for balance. At the same time there is increasing emphasis on local history and civic knowledge. In the United States, the locally produced *Michigan*, *My Michigan* and *San Francisco Today* are typical.

In countries such as Australia there is a movement to lace the English textbook with samples of native writing. Even a traditional subject may be given a national slant: *Latin for Americans*, for example, illustrates an Italian tapestry in the Cleveland Museum of Art.

Motion pictures, film strips, and tape recording, the techniques of radio and television and other audiovisual techniques and devices concern educational communications planning in the second half of the 20th century. There are still prodigious opportunities for the writer of successful textbooks. In Britain, R. J. Unstead's *Looking at History* became an educational "best seller" in the 1950s, and schoolbooks, once the preserve of teachers, increasingly attract the professional writer. This tendency receives impetus

promote it. In the U.S., the American Textbook Publishers Institute (A.T.P.I.; founded in 1942) provides a clearinghouse for publisher's and educator's ideas and plans.

In Western countries, research into the techniques of reading at the primary school level has produced elementary books in which the pages are laid out as carefully as the vocabulary is graded. Word counts dictate the material. Visual experiments decide the type. Illustration is extensively used. Some beginning readers are planned on the basis of structural linguistics and many employ the theories of programmed learning (*q.v.*). At the same time preoccupations with the mass testing of children, and in particular with the intelligence test, led some publishers in Great Britain to produce quizlike books to give the pupils practice. Criticisms have been made that in many textbooks the subject-matter was impoverished by inappropriate application of "postponement" theories of child psychology.

The growth of secondary education for all has brought a spate of schoolbooks designed for the less dedicated pupil. Academic dullness in many books has been abandoned. The pupil's interests are canvassed. Devices from the fictional approach to the strip cartoon are employed. The geography texts tend to get away from straight recitation of capes and bays and move into the social sciences.

Attempts have been made to close the gap between the textbooks and the rest of literature: publishing successes in the general trade often come out in a junior edition for schools; and reprints and paperbound editions of trade books and periodicals are also used in schools, especially at secondary and higher levels, replacing anthologies and standard texts.

The schools themselves, however, are often hampered by lack of money. In Great Britain, where books are free under the state system, the annual expenditure at the primary level by the latter half of the 20th century was scarcely 10s. per head. In the United States children in some states must still buy or rent their textbooks. Even where the books are free replacement funds are often scarce.

Cost has always been the bugbear of educational publishing.

BETTMANN ARCHIVE

TWO PAGES FROM THE "NEW ENGLAND PRIMER," 1762: (LEFT) THE ALPHABET WAS TAUGHT THROUGH THE USE OF RELIGIOUS RHYMES. (RIGHT) TITLE PAGE

Haste thee, school-boy, haste away,  
Far too long has been thy stay;  
Often you have tardy been,  
Many a lesson you've not seen;  
Haste thee, school-boy, haste away,  
Far too long has been thy stay.  
Haste thee, school-boy, haste away,  
Join no more the idler's play;

Quickly speed your steps to school,  
And there mind your teacher's rule;  
Haste thee, school-boy, haste away,  
Join no more the idler's play.  
Haste thee, school-boy, haste away,  
Learn thy lessons well to-day;  
Love the truth, and shun the wrong,  
Then no day will seem too long.

HISTORICAL PICTURES SERVICE

FROM MCGUFFEY'S "NEW THIRD ECLECTIC READER," 1857

from attempts to relate the schools to the outside world. One example is the social studies program titled "World Affairs Workshop," using paperbacks by professional writers on areas of the world, and research and information cards, biographies, and other study aids (1965; Encyclopædia Britannica Press, with The New York Times).

Nothing about textbooks is static, and their once common isolation from other teaching aids is being overcome. In the U.S., experiments in modern languages and science use the book as only one item in a comprehensive program (for example, the Biological Sciences Curriculum Study and The Physical Science Study Committee).

National anxieties, too, and the public concern for education affect the textbooks. The desire to train more technologists caused information books about science to reach junior levels where they were unknown before. Industry cooperates in the production of attractive manuals. Basic courses of the armed services in electricity and electronics have been adapted to civilian use. These things were bringing to an end the days of the school-book as something stuffy and remote from life.

(L. R. BU.; X.)

**TEXTILE PRINTING**, the process by which a decorative pattern is applied to a woven or knitted fabric in at least one colour different from the body of the fabric itself. This mode of decoration differs from the formation of a pattern by weaving and knitting processes that employ threads that are already coloured or have different capacities for taking up dyes. The four main methods of textile printing are block printing, copperplate printing, roller printing and screen printing.

### EARLY METHODS

**Block Printing.**—The origin of block printing on textiles is somewhat obscure but it is clear that the printing of textiles by means of blocks was developed from free-hand painting with a brush. Wooden blocks believed to have been used for textile printing have been found in burying grounds at Akhmim, upper Egypt, and are said to date from the 4th century A.D. No textiles printed by means of these blocks have, however, been found. In Europe, block printing of fabrics does not appear to have begun much before the end of the 12th century A.D.; the chief centre appears to have been the Rhineland of Germany.

In blocks used for printing, the spaces between the lines or devices forming the pattern were cut away, leaving the design standing in relief, as in letterpress printing. The colour was then applied to the surface of the block and the coloured block pressed down on the cloth. An interesting description of early block printing on textiles is given in *The Book of the Arts or Treatise on Printing* by Cennino Cennini, written in the late 14th or early 15th century. According to Cennini, the thickened colour was applied to the block by means of a glove, probably made of leather. The pigments were mixed with starch, gum (tragacanth) or a mixture

of these, or even with varnish, so that the colour was in a viscous state and did not run from the raised portions of the block. Cennini describes how the outlines of the patterns were printed by block and additional colours added by means of a brush. Later the colour was applied by a pad, either directly or by pressing the block down on a pad impregnated with colour. Wax resists were also printed by metal or wood blocks for indigo-resist dyeing. This method was used in Egypt in the 9th–10th century A.D. and in Germany in the 17th century. Apart from these indigo-resist dyed textiles, until the end of the 17th century all European block-printed textiles were printed with surface pigments or oil stains that were fugitive (not fast to washing). About 1676, however, more or less simultaneously in England, Holland and France, the European textile printers mastered the secrets of the complex problems of mordant dyeing with madder—the basis of the fast-dyed, hand-painted Indian chintzes that had begun to be imported into Europe during the early 17th century. Thereafter, most European block-printed textiles were produced in what was known as the "madder style."

One of the clearest expositions of block printing in the "madder style" is given in the supplement to John Barrow's *New and Universal Dictionary of Arts and Sciences* (1754). The cotton or linen was printed with chemical substances known as mordants, which on immersion in the vat reacted with the soluble dye to precipitate an insoluble colouring on the cloth fibres so that the colour remained permanently fixed in the mordant-printed areas while the dye taken up by the unmordanted parts could be easily removed by washing. In madder dyeing, different mordants can produce various shades of reds, pinks, purples and browns from a single immersion in the dye. The different mordants were printed one by one; the printer moved along the whole length of the cloth printing the first mordant from one wood block, then the second mordant from another block, and so on, until the whole pattern was completed. The mordant-printed cloth was then immersed in the dye. The reds, browns and purples were produced by printing varying strengths of alum and iron mordants, followed by immersion in the madder dye. Yellows and drabs (light, brownish colours) were produced by the printing of similar mordants followed by dyeing with weld, also known as dyer's weed. Blue was produced by "penciling-in" indigo with a brush. This operation was usually carried out by women or girls. All greens were produced by the penciling-in of indigo over yellow. To save expense, the yellows were often blocked or painted in to avoid an additional dyeing but with this method the yellow dye was fugitive and in many extant 18th-century textiles the yellow has almost entirely disappeared.

The standard method of printing madder mordants by wood block involved the use of a "tub" and a "sieve." In England the tub consisted of a sawed-off barrel but on the European continent

FROM BARROW'S "SUPPLEMENT TO THE NEW AND UNIVERSAL DICTIONARY OF ARTS AND SCIENCES," LONDON, 1754; PHOTOGRAPH BY COURTESY OF VICTORIA AND ALBERT MUSEUM

FIG. 1.—CALICO BLOCK PRINTING, 18TH CENTURY

a specially constructed square tub was more usual. The tub was filled with a viscous paste, called the "swimmings," made from discarded colour and gum; the paste provided a sort of elastic cushion on which rested the sieve, a wooden drum only fractionally smaller than the tub. The bottom of the sieve was a sheepskin, the

upper surface a tightly stretched fine woollen cloth. An assistant, known as "tireur" or "tearer," kept the upper surface of the sieve constantly and evenly supplied with the thickened mordant, which was spread on with a large brush. When the printer pressed his block on the sieve, the swimmings in the tub provided just enough "give" to ensure a satisfactory colouring-up of the block. The cloth to be printed was supported on a stone, concrete or iron structure covered with a thick blanket; this arrangement provided a firm but resilient surface so that the raised surface of the block contacted the cloth with uniform pressure over the whole area. Between the blanket and the cloth was a layer of unbleached calico (the back gray) that absorbed the mordant forced through the cloth. When the block was placed on the cloth, the printer gave it one or two sharp blows with his mallet or maul to impress the mordant firmly into the cloth. Pins known as pitch pins were inserted into each corner of the block as a guide to the printer in matching the repeats. The blocks were generally made of layers of strong durable woods, such as pear wood, arranged so that the grain in each layer ran at right angles to that in the layers above and below; this arrangement prevented warping during the successive wetting and drying. For fine details, such as thin stems and the outlines of flowers or leaves, strips of metal or metal pins were inserted into the wood blocks. Elaborate "pin grounds," also called "picoté" or "sable" grounds, were achieved by inserting metal pins into the block.

A method of mechanical block printing was invented in 1834 by a French mechanic called M. Perrot. This machine, known as the perrotine after its inventor, employed ordinary wood blocks and was widely used in the 19th century, particularly in France, for printing up to four colours. Each block of the design is impressed simultaneously in the cloth at a distance of two repeats apart. The cloth is stepped through the machine, one repeat at a time, to emerge with the full numbers of colours printed upon it. Although the original machine needed five men to tend it, one machine could print as much cloth as 24 printers and 24 assistants using hand methods. By 1836 about 60 perrotines were in operation in Europe; and even in the early 1960s when, in spite of the expense of the process, block printing continued to be used for certain classes of goods, the perrotine was not quite obsolete.

**Copperplate Printing.**—Copperplate printing on textiles was invented by Francis Nixon at the Drumcondra printworks near Dublin in 1752. Although prior to 1752 maps and embroidery designs had been printed from engraved copperplates with ordinary printer's inks, it was not until Nixon's invention that it was possible to print textile designs in fast colours by printing the cloth with thickened mordants. The designs were printed from a single engraved copperplate, usually with a repeat of about three feet square, in red, purple or sepia, using the madder dye; or in blue, using indigo, by a method known in England and the United States as "china-blue" and on the continent of Europe as "bleu d'Angleterre." This method involved printing the indigo on the cloth in an undissolved state and arranging for its simultaneous reduction and solution on the cloth after printing. This was done by immersing the printed cloth in a bath of lime (to dissolve the indigo) and a bath of ferrous sulfate (to reduce it) as many times as was necessary to achieve the desired strength of blue.

Copperplate printing was eminently suited for the production of large pictorial designs and a fineness of detail and delicacy of drawing not possible with the comparatively coarse technique of wood-block cutting. It was also used for floral designs, both for furnishing and dress, and for the printing of handkerchiefs.

The textile printer's copperplate press was little different from the heavy, flat-bed, rolling press used for the printing of engravings on paper. The plate was first inked up with the thickened mordant and then was passed through the rollers in contact with the cloth being printed. Various improvements, however, were introduced by the textile printers to make the press more suitable for their purposes. An important innovation was the "D" roller, patented by Robert Kirkwood of Edinburgh in 1803, which overcame the difficulty of getting the plate through the rollers to its original position without winding the cloth back at the same time. Kirkwood's invention consisted of substituting for the lower roller

a special roller shaved flat on one side (hence the name "D"). On the forward passage of the plate, the round part of the roller squeezed the plate up against the cloth for printing in the normal way; but on the reverse passage the roller rested with its flattened surface uppermost, thus allowing the plate to go through without touching the cloth.

With the introduction of roller printing, copperplate printing began to die out, although it continued in use, particularly for the production of printed handkerchiefs, well into the 19th century.

**Roller Printing.**—The first commercially successful patent for a roller-printing machine was taken out in 1783 by Thomas Bell, a Scotsman. So fundamental was Bell's invention that the principle of his machine has been retained throughout the numerous improvements and refinements introduced since that date. Before 1783 several attempts had been made to replace hand printing by mechanical means but none of them had been commercially successful. As early as 1743 W. Keen and M. Platt had taken out a patent for a three-colour roller-printing machine but it does not appear to have been developed. In France a textile printer named J. A. Bonvallet introduced a primitive type of roller-printing machine at his factory in Amiens about 1775. It consisted of two rollers; the upper one was made of wood, the lower one of hollow iron covered with a copper mantle on which the pattern was engraved. The lower roller was filled with red-hot iron or burning coals and revolved in a dye bath. The cloth was passed over the upper, wooden roller and the lower roller pressed up against it by means of weights, levers and a cog wheel. The machine was operated by hand. Bell's original specification (patent no. 1378, 1783) describes his invention as "a new and peculiar art or method of printing with one colour or various colours at the same time, on linnens, lawns, and cambricks, cottons, calicoes, and muslin, woollen cloth, silks, silk and stuffs, and any other species or kind of linnen cloth or manufactured goods whatever."

A second patent taken out by Bell (no. 1443, 1783) contains a similar specification for printing "one, two, three, four or five, or more colours," and by the following year he was able to put the machine into practical operation with the firm of Livesey, Hargreaves and Co. near Preston, Lancashire. Strangely enough, however, the indiscriminate use of the new machines contributed to the collapse of the firm in 1788. Bell's machine for rotary printing from engraved metal rollers was fitted with a "doctor," or steel blade, designed to remove the surface colour from the printing rollers while allowing the recessed, engraved parts to retain enough colour to print a continuous length of fabric. The machine was said to be capable of doing the work of about 40 hand printers. Although the machine was theoretically capable of printing five or six colours at a time, mechanical and chemical difficulties that existed as late as 1840 made it difficult to print more than two or three colours simultaneously. At first the new roller-printing machines were used mainly for small-scale dress prints, and it was not until the early 19th century that large-scale furnishing patterns were produced by machine. Many of the furnishing fabrics of the 1820s were produced from a single, stipple-engraved metal roller, with additional colours being printed by wood blocks or surface rollers. With James Burton's and Adam Parkinson's union-machine (1805) it was possible to print simultaneously with engraved metal and wood surface rollers. See also **TEXTILES: Printed Textiles.** (B. J. Mo.)

## MODERN INDUSTRIAL PROCESSES

**General.**—Textile printing on an industrial scale consists of two fundamental operations: (1) the impression, *i.e.*, the mechanical and physical stages in which the colouring matters are distributed on the cloth; and (2) the coloration, *i.e.*, the choice of the appropriate colouring matters (dyes, dye-generating chemicals, pigments and the necessary auxiliary chemicals), the conditions for their application, their preparation in suitable forms for presentation to the cloth and their fixation against removal during use and wear.

Textile printing in some of its aspects differs greatly from the corresponding methods for printing on paper and other materials, although the mechanical methods for bringing the colour to the surface may be similar. Inks and paints used for printing on

usually contain colouring matter in the form of pigments (finely divided solid powders insoluble in the medium by which they are applied); such pigments are attached by adhesive media to the surface to be coloured; they cannot penetrate between the molecules of the fibres. In much textile printing, however, the various coloured areas that make up the print are, in fact, dyed. The dye is dissolved, usually in water alone or in aqueous solutions containing other reagents, and the molecules thus separated can be induced to enter between the molecules of the fibre in a much more intimate association. In general, a textile print in which the coloured areas are dyed in this way may be found to be faster to washing and similar treatments than a print resulting from the use of pigment in an adhesive. The presence of adhesive may also tend to stiffen the fabric. Improvements in adhesives, however, have made it possible to obtain reasonable fastness and softness and to obtain prints of great brilliance.

Cloth, either woven or knitted, may first be singed to burn off surface fibres, desized to remove weaving sizes, scoured to take away natural impurities and the soils of manufacture, bleached to destroy residual colouring matters, impregnated with solutions of dyes or other necessary chemicals by padding, dried and, occasionally, given extra smoothness by passage through a calender. Fining may be brought about by passing the cloth over steam-heated cylinders or by running it through a stenter. The latter operation fixes the width, ensures that warp and weft are at the correct angle and renders the selvages straight and parallel. The cloth is wound under even tension on wooden shells to give cylindrical batches.

The pattern is impressed by hand blocks, stencils, silk screens or engraved or relief rollers. Drying is done in a hot flue or by steam-heated plates or cylinders. The cloth is then passed through a chamber (steamer, ager or flash ager) filled with steam. During the passage a limited amount of water condenses on the print, the dye is redissolved without being spread and the fibre swells. The dye molecules are thus enabled to penetrate into the fibre substance so that they can become fixed there. The high temperature of the steam also initiates or speeds up reactions by which some dyes are turned into soluble forms, are actually produced *in situ* from intermediates or are fixed more firmly within the fibre. Steaming for short periods is called aging or, for very short periods, flash aging. Volatile acids can be introduced into the steam (acid steaming or acid aging) if this is required. Dyes that are themselves volatile can be fixed in man-made fibres—Terylene (Dacron), Orlon, etc.—by dry heat. The adhesive medium in some pigment printing is also set by dry heat. (See also COTTON MANUFACTURE: *Converting of Cotton Goods*.)

Before and after (and sometimes instead of) steaming, the printed cloth may be passed through certain solutions, e.g., of chromates, to fix the dye. Unfixed colour may be removed by washing or soaping. This minimizes the tendency to bleed off on other cloth during wet treatments and to rub off when dry.

**Impression.**—This is the essential part of the printing operation. With several exceptions, dyes, dye-generating substances and auxiliary chemicals are dissolved or suspended in water. When applied to a fixed area of a microporous structure like cloth the solutions would spread by capillary attraction (flush) beyond the boundaries of the pattern and so give prints of unsatisfactory definition. The viscosity of the solutions is therefore increased by the addition of thickening agents. These are usually substances of high molecular weight that yield colloid dispersions in water. They include the natural starches, starches that have been altered by regulated depolymerization (for example, by the action of heat or acids to furnish dextrans), chemical derivatives of starch and cellulose, and natural vegetable gums such as gum tragacanth and gum arabic, locust-bean gum, etc. There are other vegetable mucilages, such as sodium alginate (sodium polymannuronate) from seaweed, as well as egg and blood albumin and various synthetic resin products. A more recently developed form of viscous medium is a stabilized emulsion between water and another non-miscible liquid (emulsion thickener). It is possible sometimes to use colloid aqueous dispersions of the mineral bentonite.

The thickening agent for a given printing paste is chosen for its specific thickening power, its compatibility with the dyes to be used, its freedom from interference by the other chemicals that have to be added, its stability and its general flow properties. The flow property of the entire paste is adjusted to the printing method, the shapes of the impressions to be made, the intensity of colour required, the weight and structure of the cloth, the fixation methods to be employed, and the severity of treatment that can be allowed in order to remove the exhausted paste from the print after the dyes on it have been fixed. Many dispersions of thickening agents are thixotropic; i.e., they become more fluid when they are subjected to the stresses that they receive in the printing operation, and this property has an important bearing upon the quality of the impression.

**Block Printing.**—This, the oldest method of textile printing, is also discussed above under *Early Methods*. The blocks normally consist of wood with the design carved to stand above the block surface. Alternatively, or in conjunction with these projections (pegs), fine details such as different shaped dots are provided by short lengths of copper wire (pins) of various cross section partly driven into the wood. Lines are provided by shaped copper strip (fillet) driven edgewise into the wood. Large areas of uniform colour known as blotches are produced by filling in an enclosed area with wool felt, which thus gives an extended printing surface. Areas corresponding in size to those produced respectively by pins, pegs or blotches in block printing are given the same name in screen or roller printing. Where the form of the design is suitable, where prolonged use of the block is anticipated or where a number of block sets of the same design are required, the relief printing surface may be cast in type metal. In most cases every distinct colour must be applied as a separate paste from a separate block. Further, since blocks have to be handled during the printing operation, those that are too heavy to be lifted easily are inconvenient; if the repeat of the pattern is large, more than one block may be needed for a single colour, and to print big, detailed and florid patterns the number of separate blocks may exceed 100. Block prints are thus laborious and expensive to produce but they are prized for their full, deep colourings and for the deviation from the exact design, which shows them to be "handmade." Since printing costs per yard are high, expensive cloths (e.g., heavy linens for upholstery and pure silks for dress goods) are generally chosen for block printing. Designs tend to be traditional and may be "kept on the table" for many years.

The perrotine is still used occasionally while in some firms the surface, or peg, printing machine, the forerunner of the roller printing machine (see below), is in continuous use. In this machine the circumference of one roller carries an exact number of the repeats of the pattern; a second roller guides the blanket, the back gray (back cloth) and the cloth itself and acts as the printing surface. The pegs of the patterned roller run in contact with the printing roller and are furnished by touching, at another part of the periphery, an endless band spread with paste. As with all cylinder machines, printing is continuous but the length of the repeat that can be printed is limited since the diameter of the printing cylinders cannot be increased indefinitely.

**Stencil and Screen Printing.**—The stencil printing method uses stencils made from paper impregnated with wax or from thin sheets of ductile metal. The method has been known for centuries but in modern times it has been employed only to a limited extent; some stencil printing is carried out with lacquers on nets and gauzes to give beadlike effects. The stencil may be cut from zinc foil and mounted on a frame that is laid over the fabric; the colour medium is applied through the stencil with air-spray, brush or squeegee.

Silk screen printing (*q.v.*) is the most commonly used form of what is essentially stencil printing. Fine, open-mesh gauges woven from yarns made of silk or nylon, or from fine bronze wires, are stretched with even tension upon rectangular frames of wood or light metal. The printing areas on the gauge are left open, the rest being blocked up with a lacquer. The design can be hand-painted on the screen directly with lacquer but this procedure is slow, especially for large areas, and a photographic method usually is

used. The repeat is drawn in black and white on transparent film and this serves as a negative from which a number of positives are made by the ordinary procedures of exposure and development. The positives are pieced together to make up the printing area desired in the final screen, and from the composite a full negative is made on photographic film. The screen itself is coated with a solution of gelatin to which a soluble dichromate (bichromate) has been added and is dried in the dark. It is then exposed to light behind the composite negative, and the part of the gelatin that is exposed to light becomes insoluble in water. When the negative is removed the gelatin on the unexposed areas is washed away with warm water and the deposits are reinforced by coating them with a layer of lacquer. When the lacquer is dry, the screen is ready for use. As in the other printing methods, one screen is prepared for each colour in the pattern.

Screen printing by hand is carried out on tables wide and long enough to accommodate the cloth to be treated. The tables are covered with a resilient blanket on top of which is a smooth impervious fabric. A length of the cloth is rolled off to occupy the full length of the table and is fixed to the impervious cover with starch paste or other adhesive. The screen to be printed is laid on the cloth at one end of the table, gauze side downward, with the frame therefore forming the sides of a shallow trough. Printing paste is poured into the trough and driven through the open areas with a squeegee, which is a stout strip of wood with a firm lip of rubber along the lower edge. The longest side of the screen is usually placed across the cloth (westwise), and the line in which the squeegee is moved is parallel with the shorter side. Two operatives do the printing, one at either side of the table, passing the squeegee from one to the other in the middle of the stroke. When one impression has been made with the screen, it is lifted and laid down on the next repeat, and so on, until all the cloth on the table has been printed with one colour. Then the operation is repeated, using another screen and another colour, until the full design is printed. Correct positioning of screens along the length and width of the cloth is obtained by projections on the screen frame that are made to engage with stops correctly adjusted on a metal bar (pitch rail) on one of the long sides of the table. After one table-length of cloth has been fully printed it is pulled from the table and succeeding lengths of the roll are printed by the same procedure.

Screen printing is never as swift as roller printing but the preparation of screens is easier, speedier and cheaper than the engraving of a set of copper rollers. The skill required is not nearly so great as that needed to operate a roller printing machine. While a roller printing machine can best interpret designs in which sharp definition is needed, the screen method may give superior results more easily when full colouring and a full gradation of shading is needed. There are distinctions connected with the nature of the design; e.g., it is easier to get plain longitudinal stripes by roller printing and

lateral stripes by the screen method. The screen method is better adapted for the classes of commercial printing in which short runs and quick changes of design are called for.

Many machines have been introduced to mechanize the screen printing operation. Some imitate mechanically the operations of hand printing. In others, continuous working may be achieved

by supporting the screens on rollers whose faces are perforated so that the screens can be furnished from inside; such machines approach the action of the roller printing machine.

**Roller Printing.**—This is the method by which the greatest percentage of cloth is printed. In general it is faster than other methods and produces a more accurate impression. The printing area is engraved in recess (intaglio) on a smooth copper roller. This is coated with the colour paste and then the unengraved surface is scraped clean with a steel blade (doctor), leaving the engraving filled. The roller then comes into contact with the cloth carried on a supporting roller and transfers the paste in the engraving to it. The number of engraved rollers employed depends upon the number of colours required in the design and may be from one to fourteen. With the exception of a few of continental origin, modern roller printing machines do not differ fundamentally from the one invented by Thomas Bell in 1783.

The engraved copper rollers, or shells, each rotate on a steel mandrel to which they are keyed by a tongue and groove arrangement. The drive is transmitted from one large crown wheel, driven by an electric motor, to a box wheel at the end of each mandrel. Different prints need to be printed at different speeds according to the quality of the engraving and the paste used, and the structure and composition of the cloth itself. The printing machine should be able to run at very slow speeds (inching) at the beginning of a printing in order that final adjustments in the fit of the different coloured impressions can be made before a substantial yardage of cloth has been printed.

The shells themselves are usually made of high-quality copper, but where a long life is called for, and especially where the paste contains hard, solid particles (e.g., pigments and crystals), the surface may be chromium plated. The appropriate part of the total pattern is engraved on each shell by direct manual engraving, by milling or by acid etching, including various adaptations of the photogravure process (see GRAVURE). When another pattern is desired, a new series of shells is fitted on the mandrels.
